A COMPREHENSIVE TREATISE ON INORGANIC AND THEORETICAL CHEMISTRY

By J. W. Mellor, D.Sc., F.R.S.

Vol. I.	H, O.
Vol. II.	F, Cl, Br, I, Li, Na, K, Rb, Cs.
Vol. III.	Cu, Ag, Au, Ca, Sr, Ba.
Vol. IV.	Ra and Ac Families, Be, Mg, Zn, Cd, Hg.
Vol. V.	B, Al, Ga, In, Tl, Sc, Ce and Rare Earth Metals, C (Part I).
Vol. VI.	C (Part II), Si, Silicates.
Vol. VII.	Ti, Zr, Hf, Th, Ge, Sn, Pb, Inert Gases.
Vol. VIII.	N, P.
Vol. IX.	As, Sb, Bi, V, Cb, Ta.
Vol. X.	S, Se.
Vol. XI.	Te, Cr, Mo, W.
Vol. XII.	U, Mn, Ma, and Re, Fe (Part I).
Vol. XIII.	Fe (Part II).
Vol. XIV.	Fe (Part III), Co.
Vol. XV.	Ni, Ru, Rh, Pd, Os, Ir.
Vol. XVI.	Pt and general index.

PREFACE

The first Supplement to Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry was devoted to the chemistry of the halogens, and was entitled Supplement 2, Part 1. It now appears that this description did not convey sufficiently clearly the information that it constituted the Supplement to the first part of the original Volume 2. In future, therefore, it will be known as Volume 2, Supplement 1, and the Supplement now presented will be Volume 2, Supplement 2, The Alkali Metals, Part 1, since it deals with lithium and sodium, which with potassium, rubidium and caesium occupy the second part of the original Volume 2.

Once it was realised that the extent of the information on the alkali metals to be discussed would preclude its presentation in a single supplement there seemed little reason to delay, even for a short period, the publication of that relating to lithium and sodium until the whole of the matter relating to the other alkali metals, and to the radiochemistry of the group, could also be placed in the hands of readers. The task of collecting, considering, and presenting the information of importance in the chemistry of the alkali metals which has become available since the original Treatise was published has proved formidable and unexpectedly prolonged. An attempt to survey most of the literature published during the intervening period has, however, been made, as will be evident to readers who notice the frequency with which additional references, enumerated *a*, *b*, etc., have been incorporated.

At an early stage it was recognised that although the various sections of the subject would be written by a large number of different authors according to their individual interests, knowledge, and experience, much of the material to be distributed to, and used by, them was published, abstracted and indexed with reference to the elements as a group. This circumstance, while facilitating comparative studies of the elements concerned, tended at first to clog the 'machine', and was eliminated as a major source of delay only after experience had been painfully gained. Yet another cause of delay was the death of no less than three valued contributors: Mr. F. W. James, Dr. N. Miller and Dr. P. C. L. Thorne, whose loss to the science of chemistry in general, and in particular to the editorial board responsible for the production of this volume, cannot be measured simply by reference to any scientific communications bearing their names as authors, but must take account also of much help of which this expression of thanks can be the only public recognition.

Mellor's convention, that only the hydrides, oxides, halides, sulphides, sulphates, carbonates, nitrates and phosphates of metals should be considered under the general heading of the respective metals, all other salts being discussed under the appropriate non-metallic element of the acid, has again been adopted.

The general plan on which the Supplements to Mellor's Comprehensive Treatise have been conceived and the limitations of their design, with an indication of the considerations on which invitations to contribute are based, together with some description of the mechanism employed in collecting, sifting and presenting an enormous mass of information in the form of a collection of monographs having the same general pattern but individual qualities reflecting the author's judgment, have been set out in the Preface to the Supplement on the halogens. Readers are therefore referred to that Preface if they wish to be reminded of these matters.

ACKNOWLEDGMENTS

Everyone who has been concerned with the preparation of these Supplements will join in our expression of indebtedness to all those authors, reviewers and abstractors of scientific papers whose meticulous disclosure of experimental observations, theoretical arguments, criticism, or simply presentation of relevant material in a convenient form, supply the essential foundation not merely of a work of the character of Mellor's 'Comprehensive Treatise' but of all scientific advancement. The task of preparing the Supplement devoted to Lithium and Sodium has been materially lightened by the ready collaboration of individual chemists; the Editors have also received valued encouragement and help from industrial and governmental organisations, in particular Imperial Chemical Industries Ltd., Messrs. Johnson Matthey & Co. Ltd., Associated Lead Manufacturers Ltd., The Nitrate Corporation of Chile, and the National Chemical Laboratory, especially in respect of access to sources of published information in their possession.

The Editors wish also to put on record their continuing indebtedness to Messrs. Longmans Green & Co. Ltd. for the valuable advice and assistance they have most freely rendered. They would like to thank K.W. Allen for revising the late P.C.L. Thorne's manuscript on 'The Occurrence of Lithium'.

CHAPTER I

LITHIUM

SECTION I

THE OCCURRENCE OF LITHIUM

By P. C. L. THORNE and K. W. ALLEN

Spectroscopic evidence indicates that lithium in the sun[1,2] may be largely present as the isotope ^7Li.[1] The element has also been detected in the spectra of T Tauri[3] and R Andromedae[4] and in carbon stars.[5] The number of lithium atoms in interstellar space is estimated[6] to be not more than 5×10^{-11} per c.c. The mean content of lithium in the earth's crust is estimated[7] to be 4×10^{-5}% while the abundance of lithium has also been estimated in cosmic radiation.[8] The average content of igneous rocks[9] is given as 0·014% Li_2O, while that of sedimentary rocks is 0·011%, in agreement with the geochemical cycle. The amount of lithium in sea water has been variously stated as 0·26 mg. per kg.[9] and 0·1 mg. per l.[10] The wide terrestrial distribution of lithium in relatively small quantities[11-15] is reflected in general surveys of mineral products. The minimum lithium content for economic exploitation is said[16] to be 3·5%.

The content of lithium in mineral springs in France and French possessions has been investigated by R. Bossuet[17-19] while other workers have investigated Japanese springs.[20-22] The element is also present in springs in Konya Province, Turkey, (0·36 g. LiCl/l.),[23] and Parkent (Uzbekistan) (0·9 mg. Li/l.),[24] in waters from the Turin Hills (0·01 g. Li_2O/l.)[25] and in the waters of Mondovi Lurisio (0·01–0·05 mg. Li_2O/l.),[26] and a few other places[27,28] besides the sources reported in earlier years. The brine from Searle's Lake (California) contains 0·033% of lithium chloride, the element appearing as a scale of dilithium sodium phosphate, Li_2NaPO_4, in the evaporators on concentration.[29,30] A rich source of lithium is the drainage water from the Sierra Almagrera mines[31] which contains 0·33 g. LiCl per l. It is said that from this source 3300 kg. of lithium chloride flows into the ocean per day.

The geochemistry of the formation of lithium minerals, with special reference to the Li:Mg ratio and the correlation between this and the Mn:Fe ratio, has been investigated in the Swedish deposits.[32] Variations in, *inter alia*, lithium concentrations have also been used in considering the origin of igneous rocks[33] and the use of variations in isotope ratios has been reviewed[34] with special reference to natural waters. The pegmatites of California have been studied[35] and the origin of the lithium in them has been investigated. South Dakota pegmatites have been reviewed[37] and one of them has yielded a flotation concentrate of spodumene containing 5·93% Li_2O.[38] The pegmatites in Colorado, Wyoming and Utah have been examined for lithium and this source has already been exploited.[39,40] Analyses of the Norwegian pegmatites and other lithium-bearing minerals show that many of these rocks contain more than 3% Li_2O.[41-43] In France[44,45] the production from the deposits of lepidolite at Ambazac (4% Li) and from those of amblygonite at Montebras (8·40% Li_2O) is sufficient to supply the French industries. Some lithium is found in spodumene (5·55% Li_2O) occurring at Lalin in Galizia (Spain)[46] and in the leucite of Monte Somma (Italy),[47] but the extensive **lepidolite** deposits 'Rozna' in Moravia (4·1% Li) constitute one of the most important sources of this element.[48-51] In the U.S.S.R., deposits of lithium minerals have been discovered in the North Caucasus region,[52,53] in the Ukraine[54] (with 6% Li_2O) at Altyn-Tau (with 7·54% Li_2O),[55] in E. Kazakhstan[56] in the Urals[57] and in other localities.[58] The rare lithium **amphibole**, holmquistite, has also been noted in Russia in gabbroanorthosite rocks. The crystals are columnar, 1·5-2 cm. long, with prismatic cleavage. They are bluish violet, of hardness 5-6, *d* 2·95, with characteristic pleochroism.[59] The occurrence of lithium in South Africa,[60-62] India,[63] Korea,[64] Japan[65] and U.S.A.[66-68] has been further explored: North Carolina spodumene may contain 6-7% Li_2O,[69] and that from Taos County, New Mexico, up to 10% Li_2O.[70] In Canada deposits containing up to 5% Li_2O are found in Quebec[71-74] and in Manitoba.[75-77] Although lithium minerals occur in Australia[78] there has been no production in recent years. Minerals containing lithium are also reported in various places, including Argentine,[79] Brazil[80] and Finland[81] as well as Scotland[83,84] and Northern Ireland.[85]

The presence of lithium in soils has been studied[86,87] and a content of 0·3 mg. per 100 g. is reported[88] as an average of 21 samples. In seeds[89] (40 species) the Li content is less than that of the rest of the plant and ranges from 0·01-0·13 mg. Li per kg. for cereals, and from 0·04-0·56 mg. per kg. for other species; while for cryptogams lithium is reported[90] in all samples examined, with an average value of 1 mg. Li per kg. dry material.

SECTION II

THE PREPARATION AND USES OF LITHIUM

By J. P. QUIN

THE LABORATORY PREPARATION OF LITHIUM

In the original Treatise (Mellor,II,447) metallic lithium is described rather as a chemical curiosity. This is no longer true; lithium of over 97% purity is now sold commercially and this material, either as such or after purification, is usually considered to be suitable for all normal laboratory purposes. The fact that lithium has now become a common chemical substance readily available on the market may explain why comparatively little study has been devoted recently to methods of preparing the metal in the laboratory. Nevertheless, such methods as have been used for the formation and preparation of lithium during the last thirty-five years are here described. Analytical figures showing the purity of the lithium made by the various methods are given where such information is available.

The Formation and Preparation of Lithium by Chemical Reaction.

Lithium is the first member of the group of alkali metals, which includes sodium, potassium, rubidium, cæsium and the radioactive element francium. The chemical properties of the element differ in some ways from those of the other alkali metals, and the general methods of formation and preparation of the alkali metals by chemical means, as described under the preparation of sodium (see Sect. XXIII), are not always applicable to lithium. Although lithium is readily obtained by electrolytic methods, there are circumstances in which it may be preferable to prepare the metal by chemical reaction. In general it may be said that reactions whereby lithium is produced chemically involve either the thermal decomposition of lithium compounds or the reduction of lithium compounds with metallic or non-metallic reducing agents. These reactions are preferably carried out under reduced pressure and at such a temperature that the lithium produced is removed from the sphere of reaction in the form of vapour.[1] Unlike the other alkali metals, lithium combines readily with carbon to form a comparatively stable carbide, and on this account the use of carbon or carbides, such as calcium carbide, as reducing agents is not recommended.[2,3] As will be seen by reference to the appropriate sections dealing with the alkali metal compounds, the free energies of formation of lithium compounds tend to be more highly negative than those of the corresponding compounds of the other alkali metals and this, together with the low volatility of lithium, makes the preparation of lithium by thermal routes rather more difficult than that of the other alkali metals under similar conditions.[1]

Thermal Decomposition of Lithium Salts.

The alkali metals, with the exception of lithium, have been prepared by Suhrmann and Clusius by thermal decomposition of their respective azides in vacuo. These authors state, however, that as their experiments were carried out in glass apparatus, and as lithium even below its melting point attacks glass, they did not attempt the preparation of this metal.[4] Since lithium readily reacts with nitrogen to form lithium nitride, it is unlikely that the method could be successfully adopted for the preparation of the metal, and previous workers have found that lithium azide readily explodes on heating.[5] Small amounts of lithium have, however, been formed by the thermal decomposition of lithium ferrocyanide.[6]

Thermal Reduction of Lithium Compounds with Metallic and Non-Metallic Reducing Agents.

It has been claimed that for the preparation of small quantities of lithium (not exceeding a few grams) in the laboratory, thermochemical methods involving the reduction of a lithium compound with a suitable reducing agent may offer some advantages over electrolytic methods which are more suitable for the preparation of amounts of the order of several pounds.[7]

Lithium is formed when lithium oxide is reduced with aluminium at 1150°C.[8] Under reduced pressure, below 6 mm. mercury, the metal is liberated at 750–900°C.[9] The reduction of lithium oxide with aluminium in the presence of basic oxides is discussed below (see page 7).

The preparation of lithium by reduction of lithium chloride with sodium is not satisfactory as the reaction quickly reaches an equilibrium and very little metallic lithium is produced.[14]

On a small laboratory scale lithium may conveniently be prepared by reducing lithium chloride with metallic barium.[7] Thus when barium in about 80% of the stoicheiometric requirement reacts with lithium chloride at about 850°C. at normal pressure in an inert atmosphere, lithium metal containing 5–8% of barium is obtained in about 85% yield, based on barium. Further treatment with a considerable excess of lithium chloride gives metal containing about 0·1% of barium, with total impurities amounting to 0·5%. Under these conditions the maximum yield of lithium obtained is 60%. Much of the loss of lithium is attributed to the difficulty in removing metal which is physically entrapped in the salt. The method has the advantage of avoiding the use of high vacuum and also of excessively high temperatures.

Lithium may be prepared by the Hackspill method whereby lithium compounds such as lithium chloride are reduced with calcium according to the equation:-

$$2LiCl + Ca \rightarrow CaCl_2 + 2Li.$$

A detailed description of the apparatus and the necessary procedure has been given.[10] Briefly, an intimate mixture of lithium chloride and calcium is heated in an evacuated tube when the lithium distils off and is condensed. For satisfactory results it is desirable to use an excess of calcium and the product so obtained is contaminated with about 3–4% of calcium. An excess of lithium chloride gives a dark coloured melt, which may contain a subchloride, and no lithium is obtained. Hackspill considers the method inferior to the Guntz electrolytic route to the metal, however, and does not recommend it for the preparation of lithium in the laboratory.

Lithium is not readily formed by reducing lithium compounds with iron and it has been found that when the reduction is carried out at low pressure, the lithium compounds tend to decompose or volatilize without reacting with the iron.[8,11,12]

Thus when lithium fluoride, previously dried in vacuo at 300°C., is heated under reduced pressure with excess of iron at about 1000°C., no reaction takes place. At 1200°C. the lithium fluoride volatilizes without reacting with the iron, and no lithium metal is formed. When mixtures of lithium chloride and iron are heated at 1000°C. in vacuo, the lithium chloride volatilizes unchanged and the iron is unattacked, and no lithium is formed when lithium chloride vapour is passed over iron in vacuo at 1360°C.[8] Lithium sulphate reacts with iron in vacuo at about 860°C., the melting point of the sulphate, to give a mixture of lithium oxide, ferrous and ferrosoferric oxides and iron sulphide, and no lithium is formed even when the temperature is raised to 1100°C.[8,12] Under similar conditions lithium nitrate reacts with iron at 300°C. with the formation of nitrous fumes. At a somewhat higher temperature the nitrous fumes are decomposed by iron with the formation of iron oxide and nitrogen. Reaction ceases when all the lithium nitrate has been reduced to lithium oxide, but no lithium metal is formed even when the temperature is raised to 1100°C. When lithium carbonate is heated with iron in vacuo, decomposition of the carbonate starts about its melting point, 700°C., and lithium oxide is formed, but the iron remains unattacked. Similarly when lithium hydroxide is heated with excess of iron in vacuo, evolution of hydrogen starts at about 500°C. and proceeds rapidly at 600°C. owing to the reaction:-

$$6LiOH + 2Fe \rightarrow 3Li_2O + Fe_2O_3 + 3H_2.$$

When, however, lithium oxide is heated with excess of iron in vacuo at temperatures over 1300°C. a product which consists of lithium metal much contaminated with lithium oxide distils off: this result is contrary to those obtained in previous work on the subject.[8] It has been found that lithium silicate, when reduced with iron at low pressure at 1300°C., reacts very similarly to lithium oxide, giving as the product lithium metal contaminated with oxide.[8] The preparation of lithium by the reduction of lithium sulphide with iron at high temperatures has been patented. The addition of lime or other basic oxides is recommended.[13]

Magnesium has been used to prepare lithium by the reduction of lithium compounds.[8,14] Lithium is formed when lithium oxide or hydroxide is heated with magnesium in vacuo at 550°C., but magnesium is considerably more volatile than lithium, and so tends to distil off preferentially from the reaction products.[8,14] The preparation of lithium by reducing lithium oxide with magnesium at pressures of less than 6 mm. of mercury at a temperature of 700 -900°C. has, however, been the subject of a patent.[9] When mixtures of lithium oxide, calcium oxide and magnesium are pelleted and heated in vacuo, the product that distils off is not lithium, but a lithium-magnesium alloy containing about 50% of magnesium.[14]

Lithium compounds are not readily reduced by nickel.[8] Thus when lithium chloride is heated with excess of nickel at about 900°C. under reduced pressure, the chloride volatilizes unchanged and no lithium is formed. When lithium hydroxide is heated with nickel in vacuo, lithium oxide is produced with the evolution of water vapour which then reacts with the nickel to form nickel oxide and hydrogen. When all the lithium hydroxide is transformed into lithium oxide no further reaction takes place. Lithium nitrate reacts readily with nickel under similar conditions to give nickel oxide, lithium oxide and nitrogen, but no metallic lithium is formed.

Attention has recently been directed to the preparation of lithium by reducing lithium compounds at high temperatures and low pressures with silicon, ferrosilicon or aluminium, so that the lithium metal formed distils off and is recovered by condensation.[14,19] The reduction is preferably carried out in the presence of a basic oxide such as lime.[14] Thus lithium is produced[15] when mixtures of lithium oxide and calcium oxide are briquetted with a reducing agent such as silicon or aluminium, and then heated at temperatures of 950°-1000°C. under a pressure of less than 0·001 mm. The reduction proceeds according to the equations:-

$$(1)\ 3Li_2O + CaO + 2Al \rightarrow CaO,Al_2O_3 + 6Li$$

$$(2)\ 2Li_2O + 2CaO + Si \rightarrow 2CaO,SiO_2 + 4Li.$$

The calcium oxide is added so that it may combine with the alumina or silica formed by the reaction. About 10% excess of reducing agent above the stoicheiometric proportion is required, and briquetting is essential to ensure intimate contact between the reactants. Over 75% of the lithium content of the charge is recovered when silicon is used as reducing agent, and with aluminium the recovery exceeds 80%. The use of aluminium in the reduction has the further advantage that the reaction may be carried out at a slightly lower temperature.

It is claimed that the presence of sulphate, sulphite, silica, barium, calcium and appreciable amounts of iron in the raw materials does not give rise to any trouble in the thermal production of lithium.[14] These impurities are very deleterious when making the metal electrolytically. The lithium made by the thermal route is a highly pure metal containing 0·01% of silicon, 0·01% of aluminium and 0·04% of calcium. The lithium oxide used is prepared by calcining lithium carbonate in vacuo, but attempts to carry out calcination and reduction of the oxide in a single stage, by vacuum distillation of briquetted mixtures of lithium carbonate, calcium oxide and aluminium or silicon, were unsuccessful and no lithium was obtained.[15]

The production of metallic lithium from a mixture containing 50·06% of lithium hydroxide, 14·34% of lithium carbonate, and 35·11% of water by reduction with aluminium has been described.[15a] The mixture is heated at 800°C. under a reduced pressure of 0·09–0·01mm. of mercury to give a product containing 96·02% of lithium oxide and 1·45% of lithium carbonate. This product is then reduced with 200 mesh aluminium powder at 1000°C. under a reduced pressure of 0·04–0·001mm. of mercury.

The yield of lithium so obtained varies from 24·7 to 84%. The purity of the metal is described as high; magnesium, aluminium and sodium are present only in spectrographic traces.[15a]

It has been proposed to apply vacuum metallurgy methods to the production of lithium directly from its ores such as the silicate or phosphate.[16,17] Lithium-bearing salts from Searles Lake in the United States have also been successfully reduced by this method.[19] A briquetted mixture containing the powdered ore, excess of calcium oxide and a reducing agent such as aluminium, aluminium–silicon alloy, silicon or ferrosilicon, is heated at a temperature above 900°C., preferably at 1050–1150°C., under low pressure, less than 1 mm. of mercury and preferably between 0·001 and 0·1 mm. of mercury. With lithium ore which also contains sodium or potassium, the three metals vaporize successively in the order potassium–sodium–lithium and condense at different successively higher temperatures. The potassium and sodium can thus be recovered as useful by-products. In the recovery of lithium from its phosphate ores, phosphorus volatilizes before the alkali metals and condenses at a lower temperature. Yields of approximately 90% of the lithium content of the ore have been obtained.[16] When the reduction is carried out at a pressure of 0·025 mm. using powdered spodumene briquetted with excess of calcium oxide and silicon and aluminium, yields of approximately 90% are obtained, but the metal is less pure than that obtained by the electrolytic method.[18]

The preparation of lithium by reducing lithium halides with silicon has been attempted,[14] but when a briquetted mixture of lithium chloride, calcium oxide and silicon is heated in vacuo at 850°C., no lithium metal is formed but a considerable amount of lithium chloride is volatilized from the reaction mixture. When lithium fluoride is used in place of lithium chloride better results are obtained, contrary to the experience of previous workers who found that lithium was not formed by the reduction of lithium fluoride with silicon. A briquetted mixture of lithium fluoride, calcium oxide and silicon reacts at 1100°C. under reduced pressure according to the equation:-

$$4LiF + 4CaO + Si \rightarrow SiO_2,2CaO + 2CaF_2 + 4Li.$$

No silicon tetrafluoride is formed, but the lithium metal distilling off is contaminated with lithium fluoride. The recovery of lithium is 22·7%. When aluminium is used in place of silicon, the reaction proceeds at a temperature of 1000° C. according to the equation:-

$$6LiF + 4CaO + 2Al \rightarrow Al_2O_3,CaO + 3CaF_2 + 6Li.$$

The condensed lithium metal contains 90% lithium and 10% lithium fluoride and the recovery of lithium is 44·2%.[14]

Zirconium metal in powder form has been used as a reducing agent in the preparation of lithium from lithium salts.[20] When lithium chromate and zirconium powder in the proportion 1:2 and 1:4 are heated *in vacuo* at temperatures ranging from 450° to 600°C., reduction occurs with explosive violence and lithium is formed in a 60% yield. On the other hand a 1:8 mixture reacts smoothly and quietly under similar conditions, but the yield of lithium is small. This method of preparation is considered to be suitable for making small quantities of lithium in the laboratory.

ELECTROLYTIC METHODS OF PREPARATION

Lithium from Aqueous Solutions of Lithium Salts.

It has been proposed to prepare lithium by distilling a lithium amalgam, prepared by the electrolysis of an aqueous solution of a lithium compound in the presence of mercury. The mercury volatilizes, leaving a residue of lithium metal, which, however, is likely to be contaminated with small amounts of mercury.[21] The extraction of lithium from lithium amalgam by liquid ammonia has been patented.[21a]

Electrolysis of Solutions of Lithium Salts in Non-aqueous Solvents.

Small amounts of lithium have been obtained by electrolytic deposition from solutions of lithium salts in non-aqueous solvents, but such processes do not appear to be very satisfactory for the preparation of appreciable amounts of pure lithium in the laboratory. Lithium acetylide is soluble in liquid ammonia and behaves as a weak electrolyte comparable with silver cyanide. On electrolyzing such a solution, lithium is liberated at the cathode and produces a local coloration in the solution, while small amounts of gas and carbon appear at the anode.[22]

According to a patent lithium is prepared by the electrolysis of a non-aqueous liquid comprising anhydrous liquid ammonia, methylamine, ethylamine, pyridine or mixtures of these liquids, containing a lithium salt, as for example the perchlorate or thiocyanate. Inert conductors such as iron, copper or carbon are used as cathode and carbon is the preferred material for the anode. Depending on the concentration of salt in the anhydrous liquid, which should be at least 2g.-mol. per litre, the lithium may be deposited as a colloid, suspension, paste or massive metal. It is claimed that lithium may be obtained in a high degree of purity from the deposited metal by separating it from the electrolyte and evaporating the excess solvent which is substantially free from unelectrolyzed salt.[22a]

The electrolytic decomposition of lithium salts in nitrobenzene and other organic solvents has been studied.[23-25] Electrolysis of nitrobenzene solutions of complex lithium compounds, prepared by fusing mixtures of lithium bromide or chloride with aluminium bromide or chloride, deposits lithium metal at the cathode. The use of a low current density and a diaphragm increases the yield of the metal, which is obtained at about 35% current efficiency.[24] When, however, solutions of these lithium complex compounds in benzene are electrolyzed, no lithium is deposited.[23]

Electrolytic studies of solutions of aluminium bromide–lithium chloride and aluminium chloride–lithium chloride in a number of organic solvents have been carried out under various conditions of temperature and concentration.[25] Aluminium chloride–lithium chloride solutions in nitrobenzene have a higher

Refs. p. 13

conductivity than solutions of aluminium bromide–lithium chloride and so experiments tended to be confined to the former. In the electrolysis of aluminium chloride–lithium chloride solutions in nitrobenzene, the presence of xylene improves the nature of the deposit and also the yield of metal, but as it also reduces the conductivity it is desirable to operate with not more than 3% of xylene, which is the minimum amount necessary to affect deposition favourably. When a solution containing 10% of a mixture of 0·9 moles of lithium chloride with 1 mole of aluminium chloride, 3% of xylene and 87% of nitrobenzene is electrolyzed at a current density of 0·0004amp. per sq. in., lithium is obtained at a current efficiency of 36%. By stirring the solution during electrolysis the current efficiency is raised to 40%. During electrolysis the temperature rises considerably, but by maintaining the temperature at 0°C. the current efficiency may be increased to 64%. The deposited lithium, which is preferably removed from the cathode under the protection of an inert organic liquid, is of a powdery nature and does not readily coalesce even when heated to its melting point.

Electrodeposition from these complexes has also been attempted using a number of other organic solvents in place of nitrobenzene, but no satisfactory results were obtained.[25]

Lithium has been deposited by the electrolysis of lithium iodide dihydrate in nitrobenzene, using a platinum cathode. The quality of the metal was poor.[25a]

The electrolytic separation of lithium from solutions of lithium chloride and lithium nitrate in anhydrous pyridine has been studied,[26] electrolysis being carried out at various current densities up to 0·2amp. per dm.^{2} using a mercury cathode and a platinum anode. Pyridine containing 5–10% of water was found to give results differing completely from those obtained when using anhydrous pyridine, and this is attributed to the separation of lithium hydroxide when water is present.

More recent work on the preparation of lithium by the electrolysis of solutions of lithium salts in pyridine did not give very satisfactory results. Considerable difficulty was experienced in obtaining deposits of appreciable thickness that remained untarnished, and there appeared to be a reaction between lithium and pyridine. The problem of collecting a thin deposit of the metal from the electrode was also difficult, and the method is not recommended for the preparation of the metal.[27] Lithium has been deposited in an amorphous and impure form by electrolysis of (*a*) lithium bromide, (*b*) lithium iodide dihydrate in pyridine and in quinoline.[25a] Small quantities of impure lithium appear to be formed by the electrolysis of a 25% solution of lithium bromide in ethylenediamine at 100°C., using a copper cathode with an immersed area of 2 cm.^{2}, and a lithium amalgam anode located 1cm. from the cathode.[28] With a current of 0·02amp. a brown deposit, without metallic lustre, is obtained at the cathode; this deposit reacts violently with water or with alcohol evolving hydrogen and it is suggested that it contains free lithium metal.

The electrodeposition of lithium from solutions of lithium salts in fused alkyl pyridinium halides, which may be regarded as non-aqueous solvents, has been investigated.[24] A mixture of lithium chloride and fused ethyl pyridinium bromide was electrolyzed at voltages between 6 and 12V., using a platinum cathode and a carbon rod anode. The temperature of electrolysis was about 135°C.; under these conditions lithium chloride was found to be almost completely insoluble in the bath and attempts to deposit lithium metal were unsuccessful. Similar results were obtained using lithium sulphate and lithium nitrate in place of lithium chloride.

Electrolysis of Fused Lithium Compounds.

Lithium does not appear to have been made by the electrolysis of fused lithium hydroxide as sodium is made from sodium hydroxide in the Castner cell. It has been found that lithium reacts with molten lithium hydroxide to give lithium monoxide and hydrogen, and this reaction, which takes place readily at temperatures at which electrolysis of the hydroxide may be carried out, prevents the preparation of the metal in this way.[30] It is claimed, however, that the yield of lithium in the electrolysis of fused lithium hydroxide can be increased by adding to the molten electrolyte lithium bromide, iodide or chloride in the proportion of 25-eutectic mol.%, and maintaining the bath at a temperature not exceeding 450°C.[31]

Hackspill, who had carried out extensive researches on the thermal production of the alkali metals, stated in 1928 that in his opinion no chemical method could hope to rival the electrolysis of fused lithium chloride melts for the preparation of lithium in the laboratory, and it is probable that this is equally true today for quantities exceeding a few grams.[1] In an electrolytic process the current efficiency is influenced by the solubility of the liberated metal in the electrolyte, and the solubility of lithium in fused lithium chloride has been discussed.[32]

Lithium has been prepared by the electrolysis of fused lithium chloride at 640°C. The cell operated at 4·6V. and a current density of 2–3amp./cm.^{2} The current efficiency was 68·4% and the energy efficiency 20kWh./kg. of lithium. The total time of electrolysis was approximately 3hr.[32a]

According to Guntz, lithium may be prepared very conveniently by electrolyzing a fused mixture of equal parts of lithium chloride and potassium chloride in a porcelain crucible (Mellor, II, 449).[33] The solubility of lithium in pure fused lithium chloride is high,[32] and the addition of potassium chloride to give an electrolyte which can operate at a lower temperature is likely to be beneficial. The melting point of the preferred bath is about 450°C. In one preparation an iron cathode and a carbon anode are used, and it is said that the cell does not require a diaphragm. The cell operates at 10amp. and 20V. and the product is 98–99% lithium containing 1–2% of potassium.[1]

In a modified form of the Guntz method, electrolysis is carried out in a heat-resistant steel container, heated by either gas or electricity, using a stainless steel cathode and a carbon anode.[34] It is claimed that by careful regulation of the operating conditions lithium containing only small quantities of potassium can be produced. It is, however, not possible to obtain lithium entirely free from potassium.[34a] In order to make sodium-free lithium, however, it is necessary to use an electrolyte free from sodium compounds. It is said that the electrolysis of fused mixtures of sodium chloride and lithium chloride does not yield a satisfactory product:[27] the decomposition voltage of sodium chloride is lower than that of potassium chloride, and this would result in the lithium containing larger amounts of impurity.

The preparation of small quantities of pure lithium by the electrolysis of molten lithium chloride of high purity has been described.[35] The electrolysis is carried out in a nickel crucible, with an Acheson graphite anode and an iron wire with a loop in the end for a cathode. The electrodes are separated by a partition of quartz instead of the usual asbestos board which was found to introduce impurities into the metal. The lithium chloride used in the preparation was found on spectroscopic test to contain a trace of sodium, together with smaller traces of iron, magnesium and calcium: the lithium produced on electrolysis showed, however, only a trace of sodium, the other impurities being eliminated.

The development of a miniature cell for the preparation of lithium from small amounts of lithium chloride has been described.[27] The electrolysis is carried out in a graphite container which acts as anode, using an alundum diaphragm and a stainless steel cathode. The charge is 35–40g. of lithium chloride and the yield of metal readily available is about 40% of the lithium content of the chloride; this may be increased by continued operation, at decreased efficiency. The method is recommended for the conversion of small quantities of lithium isotope compounds into lithium metal,[27] but no figures are given for the purity of the product.

It is claimed that lithium of high purity is obtained when the electrolysis is carried out in a fused bath consisting of 85–90% of lithium bromide and 10–15% of lithium chloride (Mellor, II, 449). The lithium metal made in this way was found, however, to contain 0·17% of sodium, and for many purposes this is deleterious.[36] This sodium presumably came from the lithium salts used in the electrolysis and the use of pure raw materials might be expected to yield lithium substantially free from sodium.

The electrolytic mobility of ^{6}Li in molten lithium chloride is greater by 2·2% than that of ^{7}Li, and concentrates of these isotopes have been prepared by electrolysis of the fused salt.[36a,b]

The decomposition of other lithium compounds by electrolysis has also been attempted. Thus, when fused lithium hydride is electrolyzed lithium metal is deposited at the cathode and hydrogen is set free at the anode. It is interesting to note that hydrogen is here an anion, whereas in the electrolysis of water and acids and in almost all other cases, hydrogen appears at the cathode.[37-40]

The electrolysis of fused lithium hydride has been shown to obey Faraday's law. Lithium hydride can also be electrolyzed in the solid state at temperatures much below its melting point. Thus, experiments carried out at temperatures ranging from 550° to 650°C., with a current of 2amp. at 10V., gave approximately quantitative results as measured by hydrogen evolution, though efficiencies tended to fall rapidly on continued electrolysis. The metallic lithium formed at the cathode was invariably contaminated with lithium hydride, and analysis of the product showed percentages of metallic lithium varying from 55 to 74%.[39]

There are indications that a fused melt of lithium hydride can act as an ionizing solvent and in such circumstances it may be possible to bring about the electrical decomposition of a dissolved lithium compound. Thus, for example, lithium carbide is soluble in fused lithium hydride, and when this solution is electrolyzed carbon is deposited at the anode. It is believed that this is not due to the action of hydrogen on the carbide as this can occur only at temperatures above those at which the electrolysis is carried out, and it is concluded that the carbide is ionized in the molten hydride. In these circumstances lithium should be deposited on the cathode.[40,41]

Electrolysis of Fused Salts in the Presence of a Molten Metal Cathode.

A recent patent claims the production of highly pure lithium by electrolysis of a fused lithium salt in the presence of a molten metal cathode in which lithium is soluble, followed by recovery of lithium by distilling the enriched cathode metal under reduced pressure.[42] Thus, a lithium–copper–aluminium alloy is prepared by electrolyzing a fused mixture of potassium and lithium chlorides using a 50% copper–50% aluminium alloy as a molten cathode, with a graphite anode. The cell operates at 250amp. and 5V. with a working temperature of about 750°C., and an alloy containing 4·2wt.-% (equivalent to 19·4 atomic-%) of lithium is obtained. On distilling this alloy under reduced pressure at about 870°C. the lithium content of the alloy is reduced to 0·18%. This residual lithium–copper aluminium alloy is then returned to the cell for further enrichment by electrolysis. The lithium metal obtained in the distillation is said to be of high purity. It contains 0·15% of potassium, 0·08% of calcium and 0·08% of aluminium.

A number of other alloys have been tried in place of copper–aluminium as a molten cathode. Magnesium is considered to show some promise, but the lithium content is limited to 2·4% for satisfactory working. Moreover, distillation of the lithium–magnesium alloy so prepared is said to present some difficulty.

Lithium Alloys by Electrolysis.

The solution of lithium metal in liquid ammonia, obtained by the electrolysis of a lithium salt in that solvent, may be used in the preparation of lithium alloys. Thus, for example, lithium plumbide can be prepared by reacting lead with the solution, and subsequently removing the ammonia by evaporation.[42a]

Lithium–barium–lead alloys have been prepared by the electrolysis of fused mixtures of lithium and barium chlorides in the presence of a molten lead cathode at 800°–900° C.[43] The preparation of lithium–copper–aluminium by electrolysis has been described above.

Theoretical aspects of the electrolysis of fused lithium salts have been discussed,[44] and phase diagrams have been given for fused lithium salts which may be used in the electrolytic preparation of the metal.[45] The preparation of lithium alloys is also discussed later (see page 19).

THE INDUSTRIAL PREPARATION OF LITHIUM

Lithium was first produced in appreciable quantities in 1854 by Bunsen and Matthiessen, who obtained the metal by the electrolysis of fused lithium chloride.[1] In 1893 Guntz found that the electrolysis was considerably simplified by using as electrolyte a fused mixture of lithium chloride and potassium chloride, and this bath has been used for the production of the metal on the commercial scale ever since.[2]

Lithium ores are relatively plentiful and not unduly expensive, and the preparation of the metal offers little difficulty. Moreover, lithium is the least reactive of the alkali metals and is not dangerous to handle. Nevertheless, until about thirty years ago, the metal was regarded as a chemical curiosity, and it is significant that the original Treatise, when enumerating uses for the alkali metals, did not mention a single laboratory or industrial application for lithium.

During the 1914–1919 war the Metallgesellschaft A.G. of Frankfurt, Germany, developed an aluminium-zinc alloy containing about 0·1% of lithium. Shortly after the war, the Metallgesellschaft produced an alkali hardened lead-base bearing alloy in which lithium played an essential part. These alloys were the first major industrial application of lithium and led to the production of the metal on the commercial scale in Germany.

In the United States, the manufacture of lithium by electrolysis was started a few years later,[3] and in the period 1930–1940 the world output of the metal so increased that lithium became second in importance to sodium in alkali metal production.[3] During the 1939–1945 war substantial amounts of lithium were made for the manufacture of lithium hydride which was used on an extensive scale as a convenient source of hydrogen for military purposes.[3] The lithium output in the U.S.A. in 1953 was 35 short tons. This does not include metal used in the hydrogen bomb project.[4a] The maximum lithium metal capacity for 1955 in the U.S.A. is estimated to be about 200 short tons. This is probably 85% of the world production capacity.[4b,c] No recent figures for world production are available. Several of the reviews on the production of lithium metal give extensive bibliographies.[2-6,5-14d,20]

The Manufacture of Lithium by Chemical Processes.

Attention has recently been directed towards the preparation of lithium by the reduction of lithium compounds at high temperatures under reduced pressure, so that the lithium metal formed distils off and is recovered by condensation. This method of preparation, termed vacuum metallurgy, has been the subject of a number of patents.[15,16-16c] There is, however, no evidence that such processes have as yet found any industrial application. Experimental work appears to have been confined to the laboratory or the small semi-technical scale and is discussed elsewhere (see page 6).

THE MANUFACTURE OF LITHIUM BY ELECTROLYSIS

The Electrolysis of Solutions of Lithium Salts in Non-aqueous Solvents.

As yet no process for the manufacture of lithium by electrolysis of solutions of lithium salts in non-aqueous solvents appears to have been operated commercially. However, a potential industrial route to the metal is outlined in a patent which describes the production of 10lb. of lithium per hr. by a cyclic process in a cell having an iron cathode, a carbon anode and operating at 18,000amp. and 5V., with a current density of 20amp. per sq.dm. of electrode surface. The cell feed is a liquid consisting of liquid ammonia containing 2 mols. of lithium perchlorate per litre, and the feed rate is such that the cell is supplied with 154lb. of lithium perchlorate per hr. The cathode product is a bronze coloured solution containing 12·5% by weight of lithium metal and floats on the electrolyte and is removed from the cell. The ammonia is then evaporated from the solution and recompressed for subsequent return to the cell. The anode product contains ammonia, ammonium perchlorate and lithium perchlorate. The liquid ammonia is evaporated and returned to the compressor. Water and lithium carbonate equivalent to the ammonium perchlorate are then added to the residue and ammonium carbonate obtained as a by-product. Following evaporation of the solution and drying of the salt, substantially anhydrous lithium perchlorate is obtained. Approximately 40% by weight of the lithium perchlorate feed is recycled as a result of the presence of the salt in the anolyte as it is removed from the cell. The necessary make-up ammonia is added to the recovered liquid ammonia and the cell feed prepared by mixing the required amount of lithium perchlorate and ammonia to provide a cell feed of the stated concentration.

The cell continues to operate satisfactorily when small amounts of water are present in the lithium salt which is dissolved in the anhydrous ammonia to form the electrolyte, but it is preferable to use an anhydrous salt, and means of drying the salt are described.

It is claimed that the cathode product is substantially free from an electrolyzed salt, and that metal of high purity is obtained on evaporation of the excess solvent.[16d]

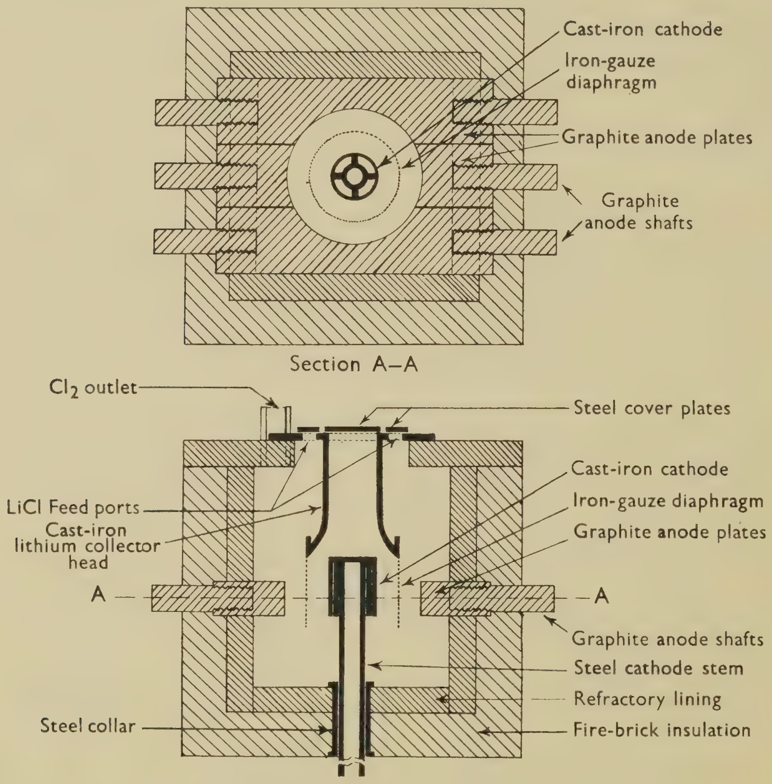
The Electrolysis of Fused Salts.

Electrolysis of a fused mixture of lithium chloride and potassium chloride appears to be the only process for the production of metallic lithium that has been operated successfully on the commercial scale.[17,18] Attempts to produce the metal continuously by the electrolysis of pure lithium chloride in the fused state have met with little success. With this electrolyte the cell voltage is found to increase rapidly with a corresponding fall in current, so that deposition of lithium soon ceases.[2] Moreover, as pure lithium chloride melts at 614°C., the operating temperature is comparatively high and both the fused chloride and the liberated lithium metal are extremely corrosive and rapidly attack the refractory lining of the cell.

The addition of potassium chloride to the bath removes these difficulties almost entirely, and the metal can be obtained in good yield by electrolyzing a fused bath consisting of equal weights of potassium and lithium chlorides.[17] The use of this mixed electrolyte has the further advantage that by selecting a melt of the required composition electrolysis can be carried out at temperatures around 400°-420° C., and at these lower temperatures the corrosive properties of the fused electrolyte and the molten lithium are greatly lessened.

The decomposition voltage of lithium chloride is lower than that of potassium chloride (*q.v.*), and it is found that the metal produced by the electrolysis of equal parts of fused potassium and lithium chlorides contains about 97% of lithium.[17]

A good deal of information has been published regarding the design and operation of a cell for the production of lithium at the Degussa plant at Rheinfelden, Germany.[17,18] The cell, shown diagrammatically in Figs. 1 and 2, consists of a square steel shell enclosing a firebrick box which serves to support and insulate the interior lining of the cell. This lining consists of a dense refractory. The cell is covered by a thick refractory plate having in the centre a large circular hole to accommodate the lithium metal collecting assembly. A smaller hole at one side of the cover plate serves for the removal of the chlorine gas produced during the electrolysis. The anode is an assembly of three horizontal graphite plates, with a circular opening in the centre of the assembly. Electrical connexion to the anode is made by six threaded graphite rods inserted externally. External electrical connexions to the source of electrical supply are conventional copper clamps and cable.



FIGS. 1 and 2. DEGUSSA LITHIUM CELL

The cathode is a vertical steel shaft attached to a hollow cast steel head. The shaft passes out of the cell through a cast steel sleeve sealed into the bottom of the cell. This serves to locate the cathode in the centre of the anode assembly. The collecting head for the lithium metal is suspended from a circular plate which covers the large opening in the cell cover plate. This head is cylindrical and has a bell shaped bottom to facilitate the collection of the globules of molten lithium deposited on the cathode during the electrolysis: its lower edge has a rim which serves to support the diaphragm. This diaphragm, which is necessary to separate the chlorine liberated at the anode from the lithium deposited at the cathode, is a cylindrical screen of 24 mesh iron wire gauze extending a little below the lower side of the anode plates. The horizontal plate carrying the collecting head has a central opening for removing the molten lithium.

During operation this opening is kept covered with a steel plate except when lithium is being removed. Two bean shaped openings alongside, also normally covered with plates, serve for adding the make up lithium chloride to the bath.

The electrolyte is a fused mixture of 52% of lithium chloride and 48% of potassium chloride. Purity of the electrolyte and the cell feed is most important, and it is desirable that the lithium chloride should be substantially anhydrous. The presence of sulphates, silica, barium, calcium, iron oxide or appreciable amounts of sodium are considered to be especially disturbing in the electrolysis, and reduce current efficiency and cell output.[19]

Recent work has shown that hydrolytic decomposition takes place during the fusion of a eutectic mixture of lithium chloride–potassium chloride containing traces of moisture if the fusion conditions are not controlled. The resultant contamination by hydroxyl ion reduces the efficiency of the mixture for electrolysis. A method of preparation involving drying under a moderate vacuum, fusion under anhydrous hydrogen chloride, and removal of hydrogen chloride from the melt, is described.[19a]

Before adding the molten electrolyte to a cell for beginning operations, the collector head and cathode are removed and the cell is heated internally. When the cell container is considered hot enough, the cathode is replaced and the cell filled with the molten electrolyte. The electrolyzing current is then turned on in the absence of the collecting head and diaphragm. After working for about two hours in this fashion, the impurities that rise to the surface of the bath are removed by skimming. The collecting head and diaphragm are then placed in position and collection of the lithium metal is started. The cell is operated continuously, lithium chloride being added at regular intervals to replace the salt electrolyzed. A small make up of potassium chloride is also necessary from time to time to maintain the composition of the cell bath at the correct concentration. The current provides the heat necessary to keep the electrolyte in the molten condition and no external heating is required. The fused electrolyte in the collecting head is covered with a layer of high-boiling petroleum oil which forms a protective coating over the lithium which accumulates in the head. From time to time the metal is removed by scooping it out with a fine wire mesh ladle, which retains the lithium but permits most of the oil to run through, though sufficient is retained to prevent ignition of the molten metal on exposure to air. The chlorine gas liberated during the electrolysis is removed under suction and absorbed in a lime suspension circulated in a packed stoneware tower.

The Degussa plant is described as consisting of six cells, each producing 8·8–11 lb. (4–5kg.) daily with a maximum output of 295 lb. (134kg.) per month. Operating details are given in Table I.

A typical analysis of the metal produced is lithium 97%, potassium 1·3%

TABLE I. - ELECTROLYTIC PRODUCTION OF LITHIUM (DEGUSSA CELL)

Temperature of electrolyte	400°–420°C.
Current load	850–900 amps.
Voltage across cell	8–9 volts
Anode current density	1·4 amp. per cm.^{2}
Cathode current density	2·1 amp. per cm.^{2}
Current efficiency	85–90%
Production per cell per day	4·5 kg.
Production per ampere hour	0·22–0·24 g.
Lithium chloride usage per lb. lithium	7·3 kg.
Electrolyte capacity of cell	100 kg.

and sodium 1·4%. The presence of even small amounts of sodium is undesirable in lithium intended for alloying purposes, and excessive amounts of sodium make the metal more easily combustible. In the early stages of the development of the manufacture of lithium, nitrogen as an impurity gave considerable trouble, the percentage present in the metal often being as high as 1%. Improved equipment and perfected methods of operation have now reduced the nitrogen content of the metal to about 0·03%.[2]

Electrolytic lithium is also manufactured in the United States, and the following description relates to a cell operated by the Lithium Corporation of America, and using as electrolyte a eutectic mixture of lithium and potassium chlorides.[20,20a] The cell is a steel box 4ft. × 6ft. in area and 3ft. deep, constructed of 1 inch boiler plate and lined with carbon blocks sealed with a carbonaceous cement. The cell body is supported in a brick lined shell and heated by gas to maintain the electrolyte in the molten condition. Four graphite anodes each 8in. in diameter and 6ft. long are supported from above and extend downward into the electrolyte. The cathodes are of steel. The cell is maintained under slight suction to remove the chlorine formed during electrolysis. In operation, the lithium metal accumulates at the cathode as drops about the size of marbles, and these quickly rise to the surface of the electrolyte and coalesce to form a pool of molten metal. It is found that a thin film of molten electrolyte forms on the surface of the lithium and protects it against atmospheric attack.

The accumulated lithium in ladled out of the cell from time to time. The metal is then allowed to cool in the ladle to a temperature below the melting point of the electrolyte but above the melting point of lithium. Thus, any electrolyte inadvertently picked up in the skimming operation solidifies in the ladle and the molten lithium, substantially free from electrolyte contamination, is then cast in ingot moulds.

The lithium is further purified by remelting at a temperature somewhat above its melting point. It is claimed that the insolubles in the metal either float to the surface, where they are skimmed off, or sink to the bottom of the pot. The molten lithium can then be tapped off through a spout set in the side of the melting furnace. During the melting a blanket of oil vapour serves to protect the surface of the molten metal from oxidation or nitriding. The cell life is about three months, after which the cell is shut down for relining. Normally the anodes last for a similar period. The cell operates at 8600 amp. and 6–6·5V., with an output of 90lb. of lithium metal per day. A typical analysis of the product is as follows: sodium 0·06, potassium 0·01, calcium 0·02, nitrogen 0·06, iron 0·001%.

The electrolysis of lithium chloride-potassium chloride melts containing lithium carbonate has been investigated by Degussa, who found that when a mixture of 48% of lithium chloride, 48% of potassium chloride and 4% of lithium carbonate was electrolyzed, preferential decomposition of the carbonate took place. Trouble was experienced during electrolysis owing to foaming of the melt and mechanical destruction of the graphite electrodes.[20b]

Little further information has been published on the technical production of lithium. The electrolysis of a fused mixture of equal parts of potassium chloride and lithium chloride has been carried out in an iron cell lined with magnesium silicate, using a graphite anode and an iron cathode. The output of the cell averages 1 kg. of lithium per day at 225amp. and 17V. The current efficiency is about 85% and analysis of the product shows that it contains 0·23% of potassium, 0·5% of sodium and 0·19% of magnesium.[21] It is stated that the magnesium comes from the cell lining and that the sodium was initially present as an impurity in the potassium chloride used in the electrolytic mixture. Another cell is described as electrolyzing a fused mixture consisting of 6 molecular parts of lithium chloride and 4 molecular parts of potassium chloride at 410°C. using graphite anodes and a hollow conical cathode.[22] The lithium produced by this cell is said to contain not more than 2% of potassium.

The electrical conductance for fused lithium chloride and lithium chloride–potassium chloride melts has been studied by a number of workers[22a-22e,22g] and the enthalpy and heat capacity of the lithium chloride–potassium chloride eutectic has been determined over the temperature range 100°–840°C.[22f]

Lithium Alloys by Electrolysis.

Osborg has developed processes for producing lithium alloys electrolytically.[23-25] Alloys of lithium and the alkaline earth metals are produced by the electrolysis of a fused mixture of lithium, potassium and alkaline earth metal chlorides in the requisite proportions. Thus, for example, a cell is operated on the commercial scale in which the initial charge of 112lb. of fused bath contains 15·5% of potassium chloride, 14·5% of calcium chloride and 70% of lithium chloride. The cell operates at 1900amp. and 9·8V., with an anode and cathode density of 0·65 and 3·75amp. per cm.^{2} respectively, and produces an alloy containing approximately 50% of lithium and 50% of calcium. An hourly make up of 885g. of calcium chloride and 1800g. of lithium chloride is added during the electrolysis.

The preparation of lithium–lead alloys by electrolysis of a eutectic mixture of lithium chloride and potassium chloride in the presence of a molten lead cathode has been investigated. Alloys containing up to 5·9% lithium were prepared. The best results were obtained at a current density of 0·2–0·9 amp./sq.cm. at 360°–500°C. At higher temperatures the yield was reduced. The current efficiencies fell from approximately 100% at 0·1amp./sq.cm. to 50% at 3amp./sq.cm.[25a]

The design of a proposed cell for the manufacture of lithium–lead alloy by electrolysis of fused lithium chloride in the presence of a molten lead cathode has been described.[25b]

Recent work shows that magnesium–lithium alloys can be made in the molten state by electrolytic deposition of lithium on a solid magnesium cathode from a molten 50% lithium chloride–50% potassium chloride, or 75% lithium chloride–25% barium chloride electrolyte at temperatures ranging from 560°C. to 630°C. By careful selection of pure raw materials and materials of cell construction it is possible to avoid contamination of the alloy with sodium, which has a deleterious effect on alloy ductility.[25c]

It is also possible to produce an alloy directly on the cathode by using a solid cathode of a metal which can combine directly with the lithium alloy produced by the electrolysis.[25] Thus, by electrolyzing a bath containing calcium, sodium and lithium chlorides in the correct proportions, using a lead cathode, a lead alloy cathode containing 0·04% of lithium, 0·6% of sodium and 0·7% of calcium may be produced; this can then be melted and cast in a form suitable for use as a bearing metal. The electrolysis may be carried out

Refs. p. 20

using a molten lead cathode. Alloys of lithium with a heavy metal having a relatively high melting point, such as nickel, are prepared by electrolyzing fused baths containing lithium compounds using anodes of nickel and graphite in parallel. The lithium alloy is deposited at the cathode. By varying the amounts of current passing through the nickel and graphite anodes respectively, nickel alloys containing between 20 and 40% of lithium have been prepared. Lithium-magnesium alloys have been prepared by electrolyzing molten lithium chloride electrolytes using magnesium cathodes.[26] With a bath of lithium chloride (60%) and potassium chloride (40%) electrolyzed at 450°C., an alloy containing 35% of lithium is produced. By operating at 550° and 600°C. alloys containing 20 and 9% of lithium respectively may be obtained. Lithium-calcium alloys have been prepared by electrolyzing a fused lithium chloride-calcium chloride electrolyte containing 10–66% of lithium chloride at 600°C. The lithium content varied between 4·8 and 33·2%.[27] Lithium alloys of zinc, aluminium and copper-aluminium have also been produced by electrolysis.[27a]

THE PURIFICATION, HANDLING AND STORAGE OF LITHIUM

The Purification of Lithium.

Unless highly purified raw materials are employed, lithium prepared in the laboratory may be expected to contain small amounts of impurities such as the other alkali metals. Crude commercial lithium contains appreciable quantities of sodium and potassium as well as other impurities. The chief impurity in sodium-free lithium is said to be nitrogen, with oxygen present to the extent of about 30 p.p.m.[1] These impurities may be undesirable if the metal is used for alloying purposes. Thus in magnesium–lithium alloys, the presence of metallic sodium is regarded as particularly deleterious.[2] Lithium of high purity now being produced on the commercial scale in the U.S.A.[3] by vacuum distillation of crude commercial lithium has a guaranteed maximum sodium content of 0·02% and normally contains 0·001% of sodium, 0·005% of potassium and 0·01% of calcium. Lithium is also being produced to the same specification with the chloride ion content limited to a maximum of 0·003%.

Little information is available on the purification of lithium by filtration of the molten metal. It has been suggested that filtration will remove the major portion of the insoluble materials from the molten metal, but the solubility–temperature diagrams for lithium oxide and lithium nitride in molten lithium do not appear to be known.[3] According to Trocki, lithium for use in a liquid metal heat transfer system may be purified by filtering the molten metal through a sintered stainless steel filter in order to remove oxide, but no figures are given for the oxygen content of the filtered product.[1]

A patent describes a method for the purification of lithium whereby impure lithium metal is placed in a metal container such as a steel tube with an opening at its lower end, and then immersed in a molten salt such as lithium chloride which does not react with lithium. The impurities in the lithium sink to the bottom of the tube and the purified metal rises to the top.[4] It is claimed that most of the volatile impurities can be removed from molten lithium by heating the metal *in vacuo* at temperatures around 400° C.[3]

Some attention has been given to distillation as a means of purifying lithium containing small amounts of sodium and potassium. Lithium containing potassium can be purified by distillation in hydrogen:[5] at 700°C. lithium hydride is formed and, being comparatively involatile under these conditions, can be freed from potassium which volatilizes. Subsequently, the pressure is reduced; the lithium hydride decomposes at 1000°C. and lithium distils over and may be condensed.

The purification of lithium may conveniently be effected by distilling the crude metal *in vacuo*.[6,11-11c] A small triple vacuum still for this operation has been described and its operation detailed.[6]

When lithium containing 0·5% of sodium is refined by distilling in argon under reduced pressure in a simple retort, the refined metal contains as little as 0·002% of sodium.[7,7a] At pressures up to 0·001 mm. the sodium content of the distillate varies little from this value, but when the pressure is increased to 0·74 mm. the sodium content of the product is quadrupled. There is little evidence of any formation of oxide, nitride or hydride when the pressures of oxygen, nitrogen or hydrogen are below 0·035 mm. The potassium content of the lithium metal distilled as above is reduced to a minimum of 0·006%.

An apparatus for the laboratory purification of small quantities of lithium by distillation has been described.[3] By operating at pressures of 10^{-5} to 5×10^{-5} mm. at temperatures of 450–500°C., lithium can be distilled at the rate of about 1 g. per hour. It is said that the pure distilled lithium so prepared does not darken on exposure to air as does the commercial metal, but retains its lustre for periods up to ten hours.

In another apparatus, with a 5 g. charge of lithium containing 2–3% of impurities, a yield of lithium (of purity at least 99·5%) equivalent to 60–70% of the initial charge is obtained in about 4 hours when distilling at a pressure of 5×10^{-5} mm. at a temperature around 500°C.[9] It is stated that when strontium is present as an impurity separation is poor because its vapour pressure curve is similar to that of lithium. The purity of the product is shown in Table II.

TABLE II.- PURIFICATION OF LITHIUM BY DISTILLATION

Constituent	Electrically Reduced Lithium		Thermally Reduced Lithium	
	Initial %	Final %	Initial %	Final %
Aluminium	>1	ND–<0·02	ND	ND–0·02
Barium	ND	ND–<0·02	0·03	<0·02
Calcium	0·05	<0·02	0·05	<0·02
Magnesium	<0·02	<0·02	0·3	<0·02–0·05
Sodium	0·5	<0·05	0·1	0·05
Silicon	0·1	<0·02	ND	ND
Strontium	ND	ND	>1	1–0·5

In the course of determinations of the heat capacity of lithium, two samples of the metal were purified by vacuum distillation in a stainless steel still at temperatures between 650 and 700°C. A chemical analysis of the first sample indicated a purity of 99·98 at.-%. In distilling the second sample the still itself was placed in a vacuum, and under these conditions lithium of 99·99 at.-% was obtained.[10]

Much of the work on the purification of lithium by distillation has been carried out in glassware, and some attention has been given to special glasses resistant to lithium.[12] Lithium reacts very strongly with glass, and glasses with lithium as the only alkali are no more resistant than ordinary soda glass. The best results are obtained by using a borate glass almost free from silica.[12] It is said that the sodium content of lithium-base alloys can be diminished by the use of a suitable flux or by bubbling nitrogen through the molten alloy.[2]

The theory of vacuum distillation of lithium has been discussed.[2a]

The Handling and Storage of Lithium.

Lithium is less reactive than the other alkali metals and can be handled at room temperatures as easily as calcium or barium. Although lithium reacts readily with water, neither the metal nor the evolved hydrogen burns spontaneously. The metal reacts slowly and preferentially with the nitrogen of the atmosphere, provided sufficient moisture is present to initiate the formation of lithium nitride.[13] The metal may be stored under oil or in an inert atmosphere.[13,14] Molten lithium is preferably prepared from dry castings.[3] The metal is generally shipped in the form of pigs which are submerged in mineral oil to avoid oxidation. If lithium has been stored under mineral oil this should be removed by washing with benzene or petroleum ether, as the metal tends to react when heated in the presence of mineral oil.[3] Lithium can however be melted and poured in an inert atmosphere such as paraffin vapour at temperatures up to 200°C.[13]

The storage of small amounts of lithium prepared in the laboratory has been described.[15] It is claimed that metal stored under mineral oil remains untarnished for periods exceeding two years. X-Ray specimens of pure lithium have been prepared by extruding the metal into vaseline to prevent oxidation, the lengths being then sealed in thin walled capillaries which were evacuated.[16]

A reactive form of lithium can be prepared by dissolving the massive metal in anhydrous liquid ammonia at low temperatures. Distillation of the ammonia from the solution leaves the lithium in a finely divided state distributed over the surface of the vessel. Nitrogen contamination amounts to less than 1%, provided sufficient time is allowed for the removal of the last traces of ammonia.[16a]

In general, molten lithium appears to be considerably more corrosive than the solid.[1,3,17,18,18a] Thus lithium severely attacks glass or the usual ceramics when melted in contact with them.[3,17] However, a technique is described for the preparation of samples of lithium in glass, whereby molten lithium is sucked into an evacuated glass capillary mould, and then frozen almost immediately before it has had time to react appreciably with the glass.[3a]

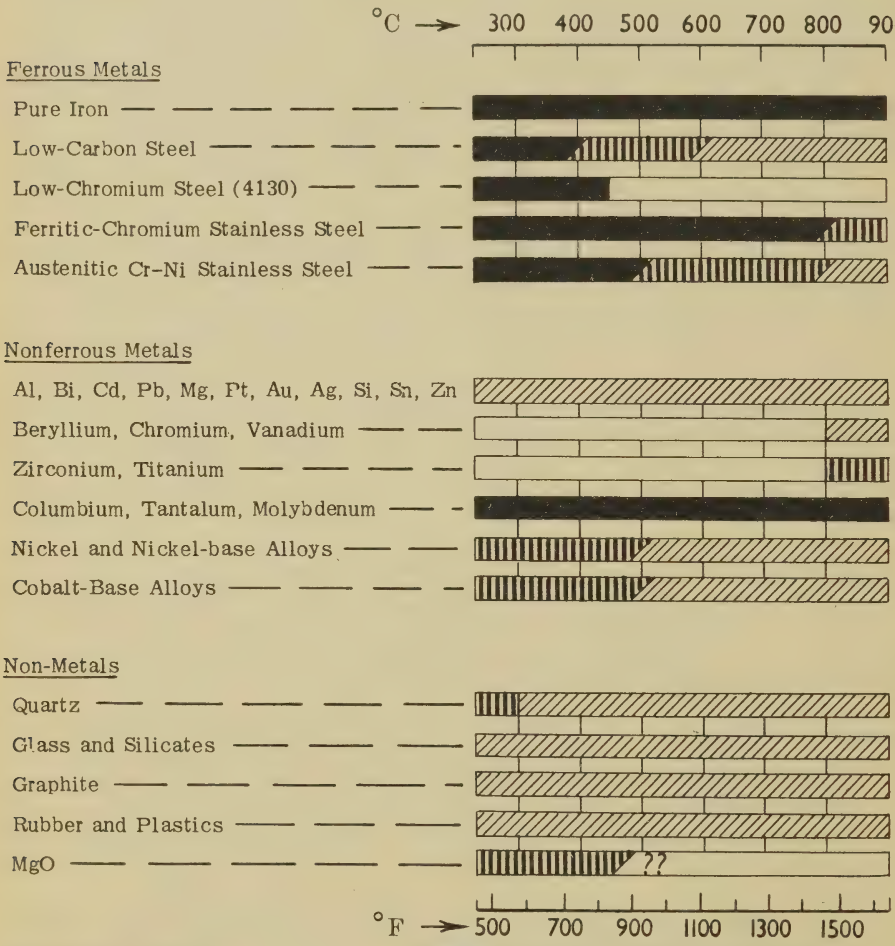
Thoroughly cleaned mild steel is recommended for handling the molten metal at temperatures up to 500°C. At higher temperatures, however, steel is rapidly attacked and decarburized by lithium.[17] It has been reported that both stainless steel and nickel are unsatisfactory for handling molten lithium but later information suggests that the trouble encountered was caused by the presence of lithium chloride or other electrolyte contamination in the lithium metal.[3] The resistance of materials to corrosion by lithium has been discussed by Miller.[17]

Armco iron has good resistance to attack by lithium at temperatures up to 600°C. and shows reasonable resistance at temperatures up to 1000°C. Nickel has good resistance to molten lithium at 225°C., limited resistance at 300°C. and poor resistance at temperatures over 600°C. Niobium, tantalum and molybdenum show relatively good resistance at 1000°C., but in the case of zirconium and titanium resistance is only fair. Aluminium, bismuth, cadmium, gold, lead, magnesium, platinum, silver, thallium, tin, zinc, manganese and silicon show poor resistance. Copper and copper alloys such as aluminium bronze, and high temperature cobalt base alloys are readily attacked by molten lithium.[17] The resistance of uranium to lithium at 600°C. has been studied.[17a]

Refs. p. 25

Many of the reported corrosion tests have, however, used commercial lithium of questionable purity, and this may have given rise to misleading results. Among the contaminants frequently found dissolved or dispersed in or combined with molten lithium are nitrogen, oxygen, chlorine and hydrogen, and these may affect the corrosive nature of the metal. Thus lithium nitride, which is readily formed by the reaction of nitrogen with solid or liquid lithium, is extremely reactive, and no metal or ceramic material has been found which shows satisfactory resistance to it, although tests have been carried out using all the common metals, and also their oxides, nitrides and silicides.[17]

TABLE III.- RESISTANCE OF MATERIALS TO LIQUID LITHIUM[17]



Resistance Ratings.

(These ratings refer to liquid-metal resistance only—not to temperature—dependent mechanical strength or metallurgical stability. See text for further discussion.)

■ — GOOD Consider for relatively long-time use.

▥ — LIMITED Short-time use only.

▨ — POOR No structural possibilities.

□ — UNKNOWN Information inadequate.

Oxygen is often present in solid lithium as the hydroxide. Molten lithium hydroxide is extremely corrosive and no refractory metal has been found suitable for handling it. On being heated above its melting point, 455°C., the hydroxide tends to decompose to form the oxide.[17]

Lithium hydroxide or oxide can combine with or flux many refractories and in this way either remove protective films from metals or in some cases, increase the thickness of the films. Molten lithium chloride attacks iron and copper, and lithium hydride is reactive with metals and ceramics at high temperatures.[17]

Attempts to melt most samples of commercial lithium in quartz result in almost immediate failure of the container but sintered quartz has been recommended for use as a container for pure molten lithium up to 285°C.[19] Resistance is said to be poor when the lithium contains lithium oxide or nitride.[17] At temperatures above 285°C. lithium silicide is formed. Molten lithium penetrates magnesium but does not otherwise attack it, whereas molten lithium attacks most oxides of other structural metals and also carbides, silicides, rubber and plastics.[17] Molten lithium reacts with cement with explosive violence and at high temperatures rapid reaction occurs with common insulating materials such as asbestos and mica, and contrary to what is said previously, magnesia (1). Molten lithium also attacks dry sand at high temperatures.[19a] Near its melting point lithium does not attack Dow-Corning Silicone D.C. 550.[17]

A number of tests have been made to determine the effectiveness of various extinguishing agents on lithium fires.[1] The dry powders tested included Pyrene GI, zirconium silicate, potassium chloride, lithium chloride and graphite. Graphite powdered to pass through a 100 mesh screen gives satisfactory control of lithium fires. Potassium chloride may also be used and is cleaner to handle. These materials must be thoroughly dry. In no case should carbon dioxide, carbon tetrachloride or acid-soda fire extinguishers be used on lithium fires owing to the danger of the formation of explosive compounds. Residues must be handled with care. Thus lithium liberates sodium from salt and soda ash, and the residue from a lithium fire may be more reactive than the original lithium. The residue from a lithium fire extinguished with graphite may form acetylene in the presence of water.[19a]

The safety precautions to be observed by persons handling lithium have been discussed.[1,3,14,14a] In this connexion it should be noted that molten lithium may burn with an intense flame when it comes in contact with moist skin.[3] A protective device for the face and head has been described.[3] An investigation into the degree of protection afforded by various materials used for fire resisting clothing showed that the only material tested which afforded any substantial protection was chrome leather.[1]

THE USES OF LITHIUM

In the original Treatise no uses are recorded for metallic lithium either in the laboratory or in industry. During the last twenty-five years, however, a large number of applications for the metal have developed in various fields of chemistry and metallurgy, though there is little information as to the actual amounts of metal assignable to the various uses. Some of the more important uses of lithium are discussed briefly below, but for more detailed information the reader should consult the original literature, and technological encyclopaedias such as Thorpe[1] or Kirk Othmer.[2] An excellent comprehensive survey of uses for lithium was published by Osborg in 1935[3] and the subject has been reviewed more recently by other authors.[4-15i]

Metallic lithium is used in the preparation of lithium compounds such as lithium hydride.[16,17] In circumstances where the weight of the standard hydrogen gas cylinder is a drawback, this compound, which can be stored and transported in light canisters, can provide a convenient source of hydrogen by reaction with water. During the 1939–1945 war considerable quantities of lithium hydride were manufactured for use in inflating military balloons. Lithium hydride has also been used as a submarine fuel by burning it with oxygen.[18]

The reactivity of lithium in organic syntheses has been contrasted with that of the other alkali metals, and comparative figures have been given for yields obtained with lithium and sodium in a number of organic reactions.[18a] Lithium can replace magnesium in the Grignard reaction, and lithium alkyls and aryls are readily obtained in this way.[3,19,20] Two important features characteristic of the lithium Grignard reaction are its vigour, and its diversity, which offer possibilities beyond the scope of the conventional magnesium Grignard reactions.

Lithium is used as a catalyst in making synthetic rubber.[20a]

The preparation of metallic powders by reducing a metal compound with the lithium addition product of the ethers of polyhydric alcohols such as glycol ether, has been patented.[21] The process has been proposed for the preparation of powdered iron, nickel, cobalt, manganese, molybdenum, zinc, tin or silver. Alloy powders or powder mixtures of these metals can also be obtained.

The production of uranium by the reduction of uranium compounds with lithium or lithium sodium or potassium alloys, has been patented.[21a]

The feasibility of titanium production by the reduction of titanium tetrachloride with lithium has been discussed.[21b]

Lithium is effective in removing nitrogen from inert gases such as helium.[22] The metal may also be used as a 'getter' or scavenger material for removing the last traces of gases from various types of vacuum tubes.[23]

It has recently been suggested that metallic lithium is used in the manufacture of tritium for use in the hydrogen bomb. Lithium-6, an abundant isotope present in natural lithium, yields tritium when bombarded with neutrons.[24]

The application of molten lithium as a rocket propellant fuel has been discussed. It would appear that lithium must be ranked as one of the best-performing fuel elements.[25]

Molten lithium offers interesting characteristics as a heat transfer fluid in high temperature systems.[26-26c] Thus lithium is the lighest metal, and has a moderately low melting point, a high boiling point, a high specific heat and a comparatively high conductivity. Its low density permits the use of high fluid velocities without encountering high pressure drop. Experience with such systems has however been limited to a few units of relatively small capacity. The design, construction and operation of a heat transfer system employing molten lithium has been described in detail.[26] The system was designed to operate with maximum and minimum temperatures of approximately 1450° F. and 677° F. respectively, and was used to determine heat transfer coefficients in a lithium-to-lithium heat exchanger at a total heat flux of 1,000,000 B.T.U. per sq. ft. per hour.

Lithium has many attractive properties as a heat transfer medium. However it has one nuclear property to which there is a major objection, and that is the high absorption cross section of the ^{6}Li isotope for thermal neutrons. This leads to inefficient utilization of neutrons produced in the fission process. Fortunately the ^{7}Li isotope, which has a natural abundance of 92·57%, has a very low absorption cross section, and may be prepared from natural lithium by isotopic separation.[26b]

The principal industrial applications for lithium lie however in the field of metallurgy. Thus the metal is used extensively as a scavenger for refining molten metals such as iron, nickel, copper, zinc and their alloys.[3,27,36,36a] The lithium may conveniently be introduced into the molten heavy metal as an alloy such as lithium calcium, which is the preferred form though master alloys consisting of lithium and the metal to be treated are also effective. These lithium alloys react readily with deleterious impurities in the molten heavy metal, such as oxygen, hydrogen, nitrogen, carbon, oxides, sulphides, sulphur dioxide or silicates. Treatment is most effective when applied immediately before pouring, and in most cases satisfactory results can be obtained by the addition of as little as 0·01–0·03% of lithium.[3] Lithium is used in the degasification of copper and has a marked effect on the conductivity of cast copper and copper wire. Thus for example as little as 0·005 to 0·01% of lithium in copper wire increases the conductivity by 20%.[31] Copper deoxidized with lithium has also good mechanical properties.[28-34]

Lithium is also used for the degasification of nickel bronze and cast monel metal.[35]

In general it may be said that heavy metals degassed with lithium show a marked improvement in their physical and mechanical properties. Grey cast iron which has been treated with lithium can be poured more readily, and shows improved machinability and tensile strength and increased hardness, though the impact strength is somewhat reduced.[36] There are indications that the yield points of carbon steels are increased by lithium treatment,[3] and stainless steels are thus improved in yield point, tensile strength, hardness and corrosion resistance, whilst carbide precipitation on solidification is radically reduced.[3]

The presence of lithium in the copper electrodes used in the fixation of nitrogen by the arc process reduces the voltage and increases the yield of nitric oxide.[37]

A number of lithium alloys are of value in engineering. In general the presence of a fraction of 1% of lithium improves the characteristics of the base metal, imparts hardness and toughness, and increases the tensile strength.[38]

During the 1914–1918 war an aluminium–lithium alloy, 'Scleron', was developed in Germany by Metallgesellschaft.[38,39] A typical composition for a 'Scleron' alloy is:-

Aluminium	83%
Zinc	12%
Copper	2%
Manganese	0·5–1%
Iron	0·5%
Silicon	0·5%
Lithium	0·1%

The physical properties of the alloy are similar to those of mild steel or brass, and its tensile strength, elastic properties and hardness are reported to be superior to those of Duralumin.[3,38,39]

The presence of lithium in magnesium improves its physical and mechanical properties:[40] binary alloys containing 11% of lithium have surprisingly good corrosion resistance.[40,41]

Lithium-containing lead alloys for bearings have been made by Metallgesellschaft since 1926.[14] The alloys are called 'B metal' or 'Bahnmetall' because they have been used extensively for railway bearings, and they contain 0·04% of lithium together with small amounts of calcium, sodium, potassium and aluminium.[14] Lithium is the most effective constituent of B metal, imparting hardness at high temperatures with high resistance to deformation and satisfactory wearing properties.[42,43] In 1943 the output of Bahnmetall was 977,000 kg.[14] The casting and physical properties of lead are considerably improved by adding 0·005% or less of lithium. Lead–lithium alloys containing small amounts of bismuth have been used for the manufacture of cable sheaths.[44] The presence of lithium improves self-fluxing brazing alloys.[44a] The addition of 0·25% of lithium to silver–copper–zinc solders improves fluidity and wetting, and also the tensile and break strengths of the joints.[45]

The use of lithium in controlling furnace atmospheres for the heat treatment of metals such as steel has been the subject of a number of patents.[46-53] It is claimed that lithium reacts with oxygen, moisture and other oxidizing gases, and so completely nullifies their destructive action on the metal under treatment. It is, however, convenient to prepare the lithium *in situ* by the

Refs. p. 29

reduction of lithium compounds with suitable reducing agents.

SECTION III

THE PHYSICAL PROPERTIES OF LITHIUM

By W.H. WILSON

Structure, Atomic and Ionic Radii, Etc.

Freshly cut surfaces of lithium are silvery-white, but they tarnish rapidly in air. When immersed in liquid nitrogen the metal remains silvery almost indefinitely;[1] specimens stored in liquid air also retain their bright metallic surfaces for a considerable time.[2] An excellent metallographic polish can be given to lithium by swabbing gently with cold methyl or ethyl alcohol.[3] The best results are obtained with methyl alcohol saturated with the reaction product, lithium methoxide. The slower reaction with higher alcohols leads to etch pitting rather than polish attack, and butyl and amyl alcohols have been used for macroetching.[3] Single-crystal specimens of lithium have been obtained by cooling the metal very slowly below its melting point.[4] Bender[5] was unable to obtain single crystal rods of lithium by methods which were successful with sodium and potassium.

At ordinary temperatures lithium crystallizes as a body-centred cube,[6-11] and the same structure exists down to the temperature of liquid air.[1,2,12] The unit cell contains two atoms and the Laue symmetry has been given as $m3m$.[11] Perlitz and Aruja[10] concluded that the space group was one of the following: T^3–$I23$, T_{α}^{3}–$I43m$, T_{h}^{5}–$Im3$, O^5–$I43$, O_{h}^{9}–$Im3m$. Several precise determinations of the unit cell dimensions at room temperature have been made recently: at 20°C. the values are 3•5023 ± 0•0002 kX. (equivalent to 3•5094 A.),[4] and 3•5016 ± 0•0002 kX. (equivalent to 3•5087 A.).[13] The small difference between these two determinations appears to be due to differences in the purity of the lithium samples. That used for the latter determination was virtually free from sodium and is claimed to be the purer material. Using 99•92% pure material, 3•5025 kX. (3•5096 A.) has been obtained at 18°C.[2] Older values of the lattice constant[6-10] – usually quoted to only three significant figures – vary between 3•50 and 3•51 A. and are in general agreement with those given above. The atomic radius is 1•52 A. Lattice parameters between room temperature and liquid air temperatures are given in Table I;[2] the variation (in kX. units) is closely represented by the equation: $a_t = a_0 (1 + \alpha t + \beta t^2 + \gamma t^3)$ where $a_0 = 3{\cdot}4992$ kX., $\alpha = 4{\cdot}6640 \times 10^{-5}$, $\beta = 3{\cdot}8791 \times 10^{-8}$, $\gamma = -11{\cdot}445 \times 10^{-11}$ and t is in °C.

TABLE I. - LATTICE PARAMETER OF LITHIUM

Temp. °C.		+20	–30	–60	–100	–140	–180	–183	–194
Lattice Parameter	(kX.)	3•5025	3•4944	3•4899	3•4847	3•4802	3•4965	3•4763	3•4755
	(A.)	3•5096	3•5015	3•4969	3•4917	3•4872	3•4835	3•4833	3•4825

Other values obtained in the region of liquid air temperature are 3•46 A. at –173°C.,[12] 3•4832 A. at –183°C.,[4] 3•4853 A. at –183°C.,[13] and 3•493 A. at

-195°C.[1]

At still lower temperatures lithium undergoes a spontaneous partial transformation to a close-packed hexagonal structure.[1,14] This transformation, which is accompanied by audible clicks, proceeds while the temperature is lowered below 72°K., but soon stops when the temperature is held constant or is raised slightly. The amount of the low temperature phase increases as the temperature is lowered and reaches approximately 50% at 63°K. Even at ~4°K. there remains a large amount of the body-centred cube structure which at this temperature has a lattice parameter of 3·472 ± 0·002 k*X*.[13] The reversion, which occurs on heating over a 30–50°C. range above 100°K., has similar characteristics, being halted by constant or lowering temperatures.[1] The exact value of the temperature required for complete reversion depends on the rate of heating and on the time during which the temperature is held above 100°K. With rapid heating the reversion is accompanied by audible clicks, but these are few or absent on slow heating. At -195°C. the unit cell dimension of the hexagonal close-packed structure is 3·086 A. and its axial ratio is 1·563.[14,15] Because of the similarity of this transformation to the change of austentite into martensite in steels, the close-packed hexagonal structure is sometimes referred to as 'lithium martensite.' The metallographic characteristics of lithium martensite have been studied.[3]

Although no spontaneous transformation occurs in lithium at liquid nitrogen temperature, a transformation from the normal body-centred cube to a face-centred cube can be induced at this temperature by cold working.[1,16] The face-centred phase forms with audible clicks during cold work at temperatures below 95°K., and its amount increases with increasing deformation below this critical value. Cold work stabilizes the body-centred form against further transformation on subsequent cooling and also against the reversion which can occur on heating to temperatures over 150°K. At -195°C. the lattice constant for the face-centred cube is 4·40 A., corresponding to an atomic radius of 1·55 A.[1] The density of this form is almost identical with that of the usual form. The expansion in atomic radius accompanying the transformation from a body-centred cube with a co-ordination number of 8 to a face-centred cube with a co-ordination number of 12 is 2·91%. Other measurements have given the lattice parameter of the body-centred and face-centred structures existing together at -194°C. as 3·4830 A. and 4·379 A. respectively.[2] When a specimen of lithium that has been compressed at liquid air temperatures and contains co-existing body-centred and face-centred structures is annealed at room temperature and then cooled to liquid air temperature, only the body-centred cube *X*-ray reflexions remain, but some of these are split into two.[2]

A suggestion that lithium crystallizes with a unit cell containing eight Li_2^+ molecules[17] is not supported by later work.[11]

Bidwell[18] observed breaks in the electrical resistance-temperature and thermoelectric power-temperature curves for lithium at a temperature of ~50°C. suggesting a phase transition (see pages 43–44). *X*-Ray diffraction experiments by the same worker indicated that the change is not from one crystalline pattern to another, but that a gradual fading-out or obliteration of the lattice structure occurs above this temperature.[19]

The atomic radial distribution curve for liquid lithium at 200°C. has been investigated by *X*-ray diffraction experiments.[20,21] At this temperature liquid lithium has 9·8 nearest neighbours at 3·24 A. compared with 8 atoms at 3·03 A. and 6 atoms at 3·50 A. in the solid.

Lithium, having the simplest electronic structure of the metallic elements, has been the subject of considerable theoretical study. It provides the closest approach to the 'ideal metal' of the electron theories since the electron cloud of the ion is small compared with the distance between atoms in the crystal. Wave-mechanical treatments of the constitution, energy and bonding of lithium have been given by numerous authors.[22-30m] A value of 3·02 A. has been estimated[31] for the lithium–lithium one-electron bond distance, and the electron distribution function for the free lithium atom[24,32] suggests a similar value of 3·2 A. Pauling[33,34] has thus pictured the lithium crystal involving both one-electron bonds and electron pair bonds, with resonance of these bonds among the various pairs of atoms. Theoretical values for many physical properties of lithium have been obtained by the application of quantum mechanical methods: in general, they are in fair agreement with experiment.

Both valence-bond and molecular orbital methods have been used in wave-mechanical treatments of the Li_2 molecule.[35-41] The Li_2^+ ion molecule has also been treated.[31,42]

Various attempts have been made to establish sets of ionic radii from which interionic distances can be obtained by summation.[33,43] Earlier attempts have been reviewed by Pauling[33] who, in formulating a semi-empirical set of such radii, selected a value of 0·60 A. for Li^+. This value was so chosen that, combined with an oxygen radius of 1·40 A., it was in agreement with the observed Li^+O^{--} distance of 2·00 A. in Li_2O. A previous treatment by Goldschmidt[44] gave 0·78 A. for the radius of the lithium ion.

Density and Thermal Expansion

The density of lithium at 18°C. has been reported as 0·5862[45] and at 20°C. as 0·546,[46] but it is probable that the density of the pure metal is more accurately represented by the much older value of 0·534 at 20°C.[47] which agrees well with *X*-ray diffraction data.[8,10] From the most recent and precise determinations of the lattice constant,[2,4,13] a value of 0·533 may be calculated for the density at 20°C. At −173°C. the density calculated from *X*-ray data is 0·553, and the same value has been given for absolute zero.[12] The atomic volume at absolute zero is 12·56 c.c.[12] Recent low temperature measurements[256] have given the density at 77°K. as 0·56 and at 4·2°K. as $0{\cdot}56_4$.

A direct determination of the density of liquid lithium at 195°C. gave 0·46 ± 0·01.[20] Values at higher temperatures are:-[48,49]

T, °C.	200	400	600	800	1000
d	0·507	0·490	0·474	0·457	0·441

Values of the coefficient of linear thermal expansion obtained from macroscopic measurements at temperatures below 0°C. are shown in Table II.[50]

TABLE II.- COEFFICIENT OF THERMAL EXPANSION OF LITHIUM

T, °K.	95	115	135	155	175	195	215	235	255	270
$\alpha \times 10^6$	17·0	23·0	28·5	32·7	36·3	39·1	41·4	43·2	44·7	45·7

Calculated values of the coefficient[50,51] are in good agreement with experiment, and there is approximate agreement with *X*-ray measurements.[13] A recent *X*-ray study[2] has given values of the mean thermal coefficient of expansion $[\alpha_{mean} = (a_t - a_0)/a_0 t]$ ranging from $3{\cdot}5 \times 10^{-5}$ at −194°C. to $4{\cdot}7 \times 10^{-5}$ at 20°C. ($4{\cdot}57 \times 10^{-5}$ at −30°C.; $4{\cdot}33 \times 10^{-5}$ at −70°C.; $4{\cdot}09 \times 10^{-5}$ at −110°C.; and $3{\cdot}81 \times 10^{-5}$ at −150°C.). From the expression for a_t (see page 31), the temperature variation of the mean coefficient of expansion is given by:-

$$\alpha_{mean} = 4{\cdot}6640 \times 10^{-5} + 3{\cdot}879 \times 10^{-8} t - 11{\cdot}445 \times 10^{-11} t^2 \ (t \text{ in °C.}).$$

Bridgman[52,53] has measured the effect of pressure on the mean linear thermal expansion over the range 0–95°C. (see Table III, page 34).

TABLE III.- EFFECT OF PRESSURE ON THE THERMAL EXPANSION OF LITHIUM

Pressure, kg./cm.^{2}	0	2,000	4,000	6,000	8,000	10,000	12,000	14,000	16,000	18,000	20,000
α(0 to 95°C.) $\times 10^5$	5·6	$5{\cdot}1_5$	$4{\cdot}7_3$	$4{\cdot}3_4$	$4{\cdot}0_0$	$3{\cdot}7_0$	$3{\cdot}4_5$	$3{\cdot}2_5$	$3{\cdot}0_6$	$2{\cdot}8_8$	$2{\cdot}7_3$

Mechanical and Elastic Properties

The extensive investigations of Bridgman have yielded data on the compressibility of lithium to progressively higher pressures as new apparatus and techniques have been developed.[46,52-59] Table IV, based on his more recent results,[56,57] gives the change in the volume at room temperature over the pressure range 0–100,000 kg./cm.^{2}.

TABLE IV.- EFFECT OF PRESSURE ON THE VOLUME OF LITHIUM AT ROOM TEMPERATURE

Pressure, kg./cm.^{2}	Relative Volume	Pressure, kg./cm.^{2}	Relative Volume
0	1·000	40,000	0·801
2,500	0·980	50,000	0·773
5,000	0·961	60,000	0·748
10,000	0·928	70,000	0·727
15,000	0·899	80,000	0·707
20,000	0·874	90,000	0·689
25,000	0·851	100,000	0·672
30,000	0·833		

The compressibilities of the five alkali metals are compared in the corresponding sub-section devoted to the physical properties of caesium. Equations have been given for the change in volume at 30° and 75°C. under pressures up to 12,000 kg./cm.^{2},[46] but these require some revision in the light of later findings.[52,60] A recent study of the compression of the alkali metals at low temperatures[256] has given the figures in Table V for the relative volume of lithium at 4·2°K.

TABLE V.- EFFECT OF PRESSURE ON THE VOLUME OF LITHIUM AT 4·2°K.

Pressure, atm.	Relative Volume	Pressure, atm.	Relative Volume
0	1·0	3,000	0·979
500	0·996	4,000	0·972
1,000	$0{\cdot}992_5$	6,000	0·960
1,500	0·989	8,000	0·949
2,000	0·986	10,000	0·939

Several authors have given mathematical treatments of the compressibility of lithium.[28,61-64]

Bridgman has also studied the shearing stress for plastic flow as a function of hydrostatic pressure.[65] The shearing strength increases with temperature, and there is a break in the shearing strength–pressure curve at a pressure of about 12,000 kg./cm.^{2} It has been suggested that this break corresponds to a change in lattice brought about by shearing stress as distinct from the more common lattice changes produced by hydrostatic pressure.[65] At a pressure of 10,000 kg./cm.^{2} the shearing stress for plastic flow is about 100 kg./cm.^{2}; at 22,000 kg./cm.^{2} it is 850 kg./cm.^{2}; and at 50,000 kg./cm.^{2} it is 3,050 kg./cm.^{2}

Young's modulus has a value[66] of $4\cdot9 \times 10^{10}$ c.g.s. or $5\cdot0 \times 10^{4}$ kg./cm.^{2} Using this figure together with compressibility data of Richards,[67] Poisson's ratio has been calculated to be 0·42.[66] Elasticity measurements have been made on lithium polycrystals with varying degrees of anisotropy, and, by extrapolation, the elastic constants of quasi-isotropic polycrystals have been obtained.[5] A study of the diffuse reflexion of *X*-rays from single lithium crystals has indicated that the relative values of the elastic constants of lithium are similar to those of sodium.[68] Quantum mechanical calculations have given the following values (in dynes/cm.^{2}) for the elastic constants of lithium at absolute zero:-[69,70]

$$C_{11} = 1{\cdot}53 \times 10^{11};\quad C_{12} = 1{\cdot}19 \times 10^{11};\quad C_{44} = 1{\cdot}329 \times 10^{11}$$

The shear constant, C_{44}, has been related to the melting point and the inter-atomic distance.[71]

No recent work appears to have been done on the hardness of lithium.

Surface Tension and Viscosity

A recent determination[72] has given 398 dynes cm.$^{-1}$ for the surface tension of lithium at its melting point, the temperature coefficient being −0·14 dynes cm.$^{-1}$ degree^{-1} between the melting point and 480°C. Previously no experimental data were available, but estimates of 430[73] and 473[74] dynes cm.$^{-1}$ had been made for the surface tension at the melting point on the basis of other physical properties of lithium; the former figure was given as the most probable after estimating surface tensions by five different methods. Wave-mechanical treatments using the free-electron model have led to values of 400,[75] 639[76] and 890[77] dynes cm.$^{-1}$ for the surface tension at the melting point.

From surface tension data for fused salts and for salts in solution, the atomic parachor of lithium has been calculated as 50[78] and 46·8[79] respectively.

Using an oscillating-sphere method, with a nickel-lined sphere, the following values have been obtained for the viscosity of lithium:-[80]

Temp., °C.	183·4	193·2	208·1	216·0	250·8	285·5
η (millipoise)	5·918	5·749	5·541	5·406	4·917	4·548

These results have been expressed by the simple equation:-

$$\eta = 13{\cdot}86 \times 10^{-4}\, e^{664/T} \quad (T \text{ in } {}^{\circ}\mathrm{K.})$$

and by the more elaborate equation:-

$$\eta v^{1/3} = 1{\cdot}999 \times 10^{-3}\, e^{1171/vT} \quad (\text{where } v \text{ is the specific volume})$$

which makes allowance for the change of volume with temperature and gives a slightly closer fit. The viscosity at the melting point is 6·02 millipoise.[80] Novikov *et al*[80a] made measurements of the kinematic viscosity ($\nu = \mu/$density) of lithium between the melting point and 770°C., there being close agreement with the results of the above workers over the limited common temperature range. Interpolated values of kinematic viscosity (ν) and viscosities derived from them using the density data already given (see page 35)are:-

Temp. °C.	200	300	400	500	600	700
ν (millistokes)	11·2	9·3	8·2	7·4	6·7	6·2
η (millipoise)	5·7	4·6	4·0	3·6	3·2	2·9

Other viscosity values extending to still higher temperatures are:-[81]

Temp. °C.	205	260	371	538	983
η (millipoise)	6·0	5·4	4·8	4·5	4·1

Melting Point and Heat of Fusion

Recent values for the melting point of lithium: 178°C.,[82] 179 ± 1°C.,[83] 179·4°C.,[84] 179·5°C.,[85] 180·2 ± 0·1°C.[45] and 183°C.,[18] are in general agreement with the best representative value of 180°C. given previously (Mellor,II, 458). The triple point of pure lithium is 180·54°C.[86,87] The widely quoted value of 186°C. for the melting point of lithium appears to be considerably too high. Melting point-pressure curves for the alkali metals are compared in the corresponding sub-section devoted to the physical properties of caesium. The lithium curve is from previously quoted determinations of Bridgman (Mellor, II, 456).

The increase in volume on fusion is 1·57% or 0·0265 c.c. per gram.[45]

Calorimetric determinations of the heat of fusion have given 690 ± 30 g.-cal./g.atom,[85] 690 ± 70 g.-cal./g.atom,[83] and 717 ± 15 g.-cal./g.atom.[86,87] An earlier paper in which heat of fusion is related to the parachor quotes 3 kilojoules/g.atom (≡ 715 g.-cal./g.atom) as an experimental value for the heat of fusion of lithium.[88] From the lowering of its freezing point on addition of sodium, the heat of fusion of lithium has been calculated as 1320 g.-cal./g. atom.[84] From freezing point data for the binary systems Li–Mg,[89,90] Li–Tl[91] and Li–Zn,[92,93] Kelley[94] calculated values of 1190, 1070 and 1080 g.-cal./g. atom, respectively, for the heat of fusion of lithium and gave a weighted mean of 1100 g.-cal./g.atom; he points out, however, that this method is not very accurate and the direct determinations are to be preferred. Taking the heat of fusion as 690 g.-cal./g.atom, the entropy of fusion is 1·52 g.-cal./deg./g. atom.[85]

Vapour Pressure and Degree of Association

Hartmann and Schneider[95] determined the vapour pressure of lithium by measuring the temperature of boiling in an argon atmosphere at pressures of 17 to 94 mm. Hg:-

t °C.	935	947	968	988	1011	1035	1079	1080
p mm. Hg	17	22	28	35	46	57	92	94

Other workers have used effusion methods to obtain vapour pressures at lower temperatures. Bogros[96-98] has given a number of values between 459 and 572°C.:-

t °C.	459	470	490	510	537	563	572
p mm. Hg	0·0010	0·0017	0·0023	0·0031	0·0080	0·011	0·017

These can be expressed within 13% by the equation:-

$$\log_{10}p(\text{mm.}) = -6110/T + 5{\cdot}39 \qquad (T \text{ in } {}^{\circ}\text{K.}).$$

In studying the degree of association of alkali vapours, Lewis[99] obtained values for the vapour pressure of lithium in the region of 600°C. and gave the equation: $\log_{10}p(\text{mm.}) = -8090/T + 8{\cdot}505$ (T in °K.). This equation gives higher vapour pressures than have been found by other workers; the higher values have been ascribed[100,101] to the presence of sodium in the metal used. Using lithium from the same source but after heating it at 650°C. for a prolonged period to remove sodium, the following results have been obtained:-[100,101]

t °C.	462	476	497	515	538	550
p mm. Hg	0·0008	0·0013	0·0036	0·0044	0·0075	0·0134
t °C.	563	576	595	610	642	
p mm. Hg	0·0170	0·0232	0·0483	0·0599	0·1564	

These can be expressed by the equation:-

$$\log_{10}p(\text{mm.}) = -8172/T + 8{\cdot}012 \ (T \text{ in } {}^{\circ}\text{K.}).$$

In a review of vapour pressure data (1941) the equation:-

$$\log_{10}p(\text{mm.}) = -8143/T + 8{\cdot}0 \ (T \text{ in } {}^{\circ}\text{K.})$$

has been given as representing the vapour pressure of lithium within ± 10% between 1100 and 1400°K. and within ± 30% between 700 and 1600°K.[102]

The equilibrium constant for the dissociation of lithium molecules into atoms has been computed from spectroscopic data; the following values are for partial pressures in atmospheres:-[103]

T°K.	298·1	500	1000	1600	2000
$\log K = \log (P_{\text{Li}})^2/P_{\text{Li}_2}$	−15·540	−7·539	−1·570	+0·697	+1·456

By applying these results to the vapour pressure observations of Hartmann and Schneider,[95] the pressure of the lithium atoms has been represented by the equation:-

$$\log_{10}p_{\text{Li}}(\text{mm.}) = 11{\cdot}889 - 38{,}900/4{\cdot}575T - 1{\cdot}174 \log T.$$

At the predicted boiling point of 1599°K., the partial pressures of lithium atoms and molecules in the saturated vapour are 648 mm. and 112 mm. respectively. The experimental values of the equilibrium constant obtained by Lewis[99] in the region of 900°K. using a magnetic deflexion method are considerably greater than those given above. Lewis's values given for partial pressures in mm. are:-

T, °K.	852	876·5	902	909	926·5
log K.	0·967	1·209	1·352	1·478	1·516

The heat of dissociation of the lithium molecule as calculated from these equilibrium constant data is 24·0 kg.-cal.[99]

Boiling Point, Heat of Vaporization

By extrapolation of vapour pressure data obtained at lower temperatures, the boiling point of lithium has been given as 1609 ± 5°K.,[95] 1530°K.[100] and 1590°K.[102]

A value of 22·03 has been given for Trouton's constant.[95] Estimates of the critical temperature and the chemical constant based on vapour pressure data are 2490°K. and 3·08 respectively.[95]

The latent heat of vaporization of lithium has been calculated by several workers from their vapour pressure measurements at various temperatures. Reported values, with the temperature range of the vapour pressure measurements shown in brackets, are 35·4 kg.-cal./g.atom[94] (935–1080°C.); 37·0 kg.-cal./g.atom[99] (~580–650°C.); 28·0 kg.-cal./g.atom[98] (459–572°C.); and 36·6 kg.-cal./g.atom[100] (462–642°C.). Utilizing the vapour pressure data of Hartmann and Schneider,[95] Kelley[104] has represented the heat of vaporization by the equation:-

$$\Delta H \ (\text{g.-cal./g.atom}) = 36{,}410 - 2{\cdot}53T,$$

and the free energy of vaporization by:-

$$\Delta F^{\circ} \ (\text{g.-cal./g.atom}) = 36{,}410 + 5{\cdot}83 \ T \log T - 40{\cdot}88 \ T.$$

At the boiling point (1645°K.), ΔH = 32,248 g.-cal./g.atom and ΔS = 19·6 g.-cal./g.atom/°K.[104] Computation of the latent heat of vaporization of lithium from the absorption spectra of the lithium halides has given a mean value of 29·6 ± 0·6 kg.-cal./g.atom.[105,106]

The U. S. Bureau of Standards[107] selected value (1952) for the heat of sublimation of lithium to monatomic vapour is 36·49 kg.-cal./g.atom at 0° K. and 37·07 kg.-cal./g.atom at 298·16° K., while the free energy of sublimation is 29·19 kg.-cal./g.atom at 298·16° K. A later publication[107a] gives the heat of sublimation to monatomic vapour as 38·05 kg.-cal./g.atom at 0° K. and 38·439 kg.-cal./g.atom at 298·16° K., and the free energy of sublimation as 30·57 kg.-cal./g.atom at 298·16° K. Kelley[104] gave 36·439 kg.-cal./g.atom for the heat of sublimation at 298·1° K. Quantum mechanical calculations of the heat of sublimation or cohesive energy are in fair agreement with these figures.[28,30e,30i,108-110]

Specific Heat, Heat Content and Entropy

Specific Heat.

The specific heat of lithium between 15° K. and room temperature has been measured by Simon and Swain.[111] Some of their values are given in Table VI (see below). Recent measurements[111a] of the specific heat between 1·5° K. have given the following results:-

T, °K.	1·5	2·0	2·5	3·0	3·5
C_p, g.-cal./g.atom/°C.	0·00066	0·00091	0·00127	0·00150	0·00186
T, °K.	4·0	5·0	6·0	7·0	8·0
C_p, g.-cal./g.atom/°C.	0·00227	0·00335	0·00491	0·00684	0·0091
T, °K.	9·0	10·0	12·0	18·0	20·0
C_p, g.-cal./g.atom/°C.	0·0119	0·0152	0·0238	0·0722	0·0953

Several series of measurements were made on the lithium sample, and reproducible results were obtained between 2·4° K. and 13° K. and above 17° K.: there was some lack of reproducibility below 2·4° K. and between 13° and 17° K. The value for the atomic heat at 20° K. agrees very well with that of Simon and Swain.[111] A plot of C_p/T against T^2 for the above results leads to $(0{\cdot}418 \pm 0{\cdot}008)T \times 10^{-3}$ g.-cal./g.atom^{-1}deg.$^{-1}$ for the electronic specific heat.[111a]

From cooling curves obtained in studying the thermal conductivity of lithium, Bidwell[112] calculated specific heats from 140°C. down to liquid hydrogen temperatures. The values are in fair agreement with those in Table VI over most of the range, although at the lowest temperatures Bidwell's values are considerably higher. At temperatures above +75°C. the atomic

TABLE VI. - THE SPECIFIC HEAT OF LITHIUM AT LOW TEMPERATURES

T(°K.)	Atomic Heat (g.-cal./g.atom)		T(°K.)	Atomic Heat (g.-cal./g.atom)	
	C_p	C_v		C_p	C_v
15	0·045		140	4·08	4·01
20	0·095		160	4·43	4·34
25	0·169		180	4·68	4·57
30	0·273		200	4·92	4·78
40	0·573		220	5·15	4·94
50	0·996	0·995	240	5·28	5·09
60	1·43	1·42	260	5·44	5·22
80	2·32	2·31	280	5·56	5·31
100	3·05	3·02	300	5·66	5·39
120	3·64	3·59			

heat at constant volume exceeds the Dulong and Petit maximum of 5·95, and it has been suggested that the excess is latent heat of crystallization required for disintegration of the crystal lattice.[112] Other workers[113] have determined C_p over a 180° range immediately below the melting point; the value at the melting point was 7·1 g.-cal./g.atom. There is a rise in the specific heat immediately below the melting point which is characteristic of the alkali metals; it is, however, less marked with lithium than with sodium or potassium. In reviewing high temperature thermal data up to 1933, Kelley[114] gave the equation:-

$$C_p = 0{\cdot}68 + 18{\cdot}0 \times 10^{-3}T \qquad (C_p \text{ in g.-cal./g.atom, } T \text{ in } ^\circ\text{K.})$$

as applying between 273 and 459°K. with an estimated accuracy of ± 10%. In a more recent publication the same author gives:-[115]

$$C_p = 3{\cdot}15 + 8{\cdot}40 \times 10^{-3}T \text{ (accuracy } \pm \text{ 3\% between } 298^\circ \text{ and } 452^\circ\text{K.)}$$

for solid lithium, and:-

$$C_p = 8{\cdot}93 - 0{\cdot}36 \times 10^5 T^{-2} \text{ (accuracy } \pm \text{ 1\% between } 298^\circ \text{ and } 2000^\circ\text{K.)}$$

for diatomic lithium vapour.

In recent years several American workers have measured the specific heat of lithium at high temperatures. The calorimetric results of Bates and Smith[116] (500–1000°C.), Redmond and Lones[117] (200–1100°C.) and Douglas *et al.*[86,87] (m.p. to 900°C.) are reasonably concordant, while values obtained by Cabbage[118] (m.p. to 1000°) are considerably lower than those of the other workers for temperatures above 500°C. and exceed them at lower temperatures. Values of the heat capacity between 200° and 500°C. computed by Yagee and Untermeyer[119] from measurements of the relative cooling rates of lithium and aluminium also diverge from those of the above workers, being lower at 200° and higher at 500°C. Douglas *et al.*[86,87] give the following equations for the heat capacity in absolute joules per gram, t being in °C.:-

$$C_p \text{ (solid)} = 3{\cdot}510 + 9{\cdot}25 \times 10^{-4}t + 3{\cdot}312 \times 10^{-5}t^2 - 8{\cdot}88 \times 10^{-8}t^3 \quad (25^\circ \text{ to } 180{\cdot}54^\circ\text{C.})$$
$$C_p \text{ (liq.)} = 4{\cdot}5306 - 8{\cdot}38 \times 10^{-4}t \quad (180{\cdot}54^\circ \text{ to } 421{\cdot}8^\circ\text{C.})$$
$$C_p \text{ (liq.)} = 4{\cdot}2076 - 7{\cdot}23 \times 10^{-5}t \quad (421{\cdot}8^\circ \text{ to } 895{\cdot}3^\circ\text{C.}).$$

Values at rounded temperatures are shown in Table VII together with other thermodynamic functions.[86,87] Simon and Swain's value[111] at 25°C., the only temperature common to both, is about 4% lower than that from the above equation.

Measurements by these two sets of workers of the heat capacity of synthetic sapphire over the common temperature range 140–280°K. also differed by the same amount, and Douglas *et al.* have used this relationship to apply corrections to the values of Simon and Swain. These corrected values have been used in calculating the standard molal enthalpy and entropy at 25°C. (see below). Heat capacities calculated from spectroscopic data for monatomic and diatomic lithium vapour are shown in Table VIIa.[107a]

The specific heat of lithium does not obey the Debye formula. Instead, the Debye characteristic temperature, θ, increases from a value of 328 at 15°K. to 430 at 300°K.[111] This anomalous behaviour has been the subject of much theoretical study. Simon and Swain[111] suggested that the change of θ with temperature could be explained by thermally excited transitions to some higher quantum level. Subsequent direct measurements of the thermal oscillations in lithium have shown, however, that between −190°C. and room

TABLE VII. - THERMODYNAMIC FUNCTIONS OF LITHIUM BETWEEN 298° AND 1200°K.

1200	6·668	17·836	11·168	6·868

temperature the energy supplied to lithium goes entirely to atomic vibration and not to a quantum jump.[120,121] Following the generalized work of Blackman,[122] showing that changes of θ with temperature could be accounted for by a theory of specific heats which takes into account the atomic structure, Fuchs[69] has shown that if dispersion is neglected – as is the case in the Debye theory – the anisotropy of the alkali metals gives rise to the type of divergence from the Debye formula observed with lithium. Specific heats in fair agreement with the experimental values of Simon and Swain[111] have been calculated by evaluating the four discrete frequencies of atomic vibration in terms of the elastic constants of the lithium crystal and representing the residual degrees of freedom not covered by these modes by a Debye function with a correspondingly reduced characteristic temperature.[123]

Characteristic temperature values for lithium have been given by a number of authors in treatments of specific heat and other data.[5,50,68,69,111,111 a,121,122,123 a-c] A recent detailed study of characteristic temperature data has used several methods for calculating θD, the Debye characteristic temperature, from thermodynamic data and θR from electrical resistance data.[124] θR exhibits a maximum in the region of 80° to 100°K. although no discontinuity or anomaly is apparent in the resistance–temperature curve itself: θD shows no such maximum. While theory predicts that θD should be less than θR, the reverse applies for lithium above 100°K. At room temperature θR and θD have values of about 330 and 400 respectively.[124] When, in a later paper,[125] an allowance was made for the effects of thermal expansion, the value of θR was increased by about 20.

Heat Content or Enthalpy.

Using data available up to 1948, Kelley[115] formulated the following equation to represent the heat content or enthalpy of solid lithium between 298 and 452°K. with an accuracy of ± 3%:-

$$H_T - H_{298\cdot16} = 3\cdot15T + 4\cdot20 \times 10^{-3}T^2 - 1313 \text{ (}H\text{ in g.-cal./g.mole, }T\text{ in °K.).}$$

From vibration frequency data[126] the same author represented the heat content of lithium vapour between 298 and 2000°K. with an accuracy of ± 1% by the equation:-

$$H_T - H_{299\cdot16} = 8\cdot93T + 0\cdot36 \times 10^5 T^{-1} - 2783,$$

* in g.-cal./mole/°K.

the heat content being in g.-cal./g.mole, and T in °K.[115] Calorimetric measurements over the range 500 to 1000°C. have led to the equation:-

$$H_t - H_0 \text{ (g.-cal. per gram)} = 121 \pm 39 + 0{\cdot}962\ (\pm\ 0{\cdot}05)T$$

as representing the heat content of liquid lithium with a confidence limit of 95%.[116] More recent measurements on lithium of 99·98–99·99 atomic per cent purity, using an ice calorimeter and a drop method over the range 50 to 900°C., have given the following equation in which the heat content is in absolute joules per gram and t is in degrees C.:-[86,87]

$$H_t \text{ (solid)} - H_0 \text{ (solid)} = 3{\cdot}5096t + 4{\cdot}625\ (10^{-4})t^2 + 1{\cdot}1041\ (10^{-5})t^3 - 2{\cdot}221\ (10^{-8})t^4 \text{ (25 to 180·54°C.)}$$

$$H_t \text{ (liquid)} - H_0 \text{ (solid)} = 318{\cdot}07 + 4{\cdot}53026t - 4{\cdot}191\ (10^{-4})t^2 \text{ (180·54 to 420°C.)}$$

$$H_t \text{ (liquid)} - H_0 \text{ (solid)} = 386{\cdot}21 + 4{\cdot}20755t - 3{\cdot}615\ (10^{-5})t^2 \text{ (420 to 900°C.)}$$

From the low-temperature heat capacity data of Simon and Swain,[111] adjusted as described above, the heat content of solid lithium at 298·16°K. relative to that at 0°K. is 1090 g.-cal./g.atom.[86,87] Values of the heat content function based on the above equations and this value for 298°K. are given in Table VII (see page 40). The best single equation representing the heat content of liquid lithium (in absolute joules per g. at T°K.) between 453·70° and 1173°K. is:-[86]

$$H_T \text{ (liquid)} - H_{273\cdot16} \text{ (solid)} = -275{\cdot}73 + 3{\cdot}52675T + 3{\cdot}94442\ (10^{-4})T^2 - 9{\cdot}5669\ (10^{-8})T^3 - 1{\cdot}24649/T.$$

Heat content functions, calculated from spectroscopic data, for monatomic and diatomic lithium vapour are shown in Table VIIa together with other thermodynamic properties.[107a] The same source[107a] gives the heats of formation of monatomic and diatomic lithium vapour at 0°K. as 38·05 and 50·34kg.-cal./g.mole respectively.

Entropy.

Extrapolation of the low-temperature heat capacity data of Simon and Swain[111] leads to 6·70 ± 0·06 g.-cal./g.atom/°K. for the entropy of solid lithium at 298·16°K. After adjusting the same heat capacity data, as described above, Douglas and co-workers obtained $S_{298\cdot16}$ = 6·78 g.-cal./g.atom/°K.[86,87] Entropies for solid and liquid lithium obtained from calorimetric measurements up to 1200°K. are also shown in Table VII.[86,87]

For monatomic lithium vapour, the Sackur equation – to which must be added $R\ln 2$ to account for the multiplicity in the lowest energy state – gives 33·15 ± 0·01 g.-cal./g.atom/°K. for the entropy at 298·16°K.[127] The molecular constants of diatomic lithium vapour lead to $S^{\circ}_{298\cdot16}$ = 46·98 ± 0·10 g.-cal./mole/°K. of which 1·17 is the vibrational contribution and 45·81 the translational and rotational contribution.[127] Table VIIa contains entropy values for monatomic and diatomic lithium vapour calculated by Hall *et al.*[107a] in a recent survey of the thermodynamic properties of lithium and other alkali metals.

Thermal Conductivity

A modified Forbes bar method has given the values for the thermal conductivity of solid lithium shown in Table VIII.[112]

TABLE VIII.- THERMAL CONDUCTIVITY OF SOLID LITHIUM

Temp., °C.	−250	−200	−150	−100	−50	0	+50	+100	+150
k, g.-cal.sec.$^{-1}$cm.$^{-1}$°C.$^{-1}$	1·00	0·218	0·200	0·185	0·170	0·155	0·153	0·166	0·170

From 0 to −200°C. the thermal conductivity increases linearly, but with further decrease of temperature it rises sharply. A minimum thermal conductivity occurs at +40°C.; this point corresponds to breaks in the electrical resistance-temperature and thermoelectric power-temperature curves (see Fig. I, page 44). Between 80° and 120°K., MacDonald *et al.*[127a] obtained a thermal conductivity of about ·1 watt cm.$^{-1}$°C.$^{-1}$ (equivalent to 0·24 g.-cal.sec.$^{-1}$cm.$^{-1}$ °C.$^{-1}$). At lower temperatures it rose to a maximum of 5 to 7 watt cm.$^{-1}$ °C.$^{-1}$ at around 20°K. An earlier study of the thermal conductivity of lithium using an indirect method involving the measurement of the electrical resistance of a lithium wire and its temperature coefficient of resistance gave k_t/k_0 = 2·9 at −253°C.; 1·16 at −182°C.; 1·02 at 20°C.; and 1·02 at 101°C.[128] The absolute value at 0°C. was estimated to be 0·17 g.-cal.sec.$^{-1}$cm.$^{-1}$ °C.$^{-1}$ [131]

Measurements of the thermal conductivity of lithium[119] relative to that of sodium when taken in conjunction with other measurements of the thermal conductivity of sodium[129] lead to a value of 0·09 g.-cal.sec.$^{-1}$cm.$^{-1}$°C.$^{-1}$ for the thermal conductivity of liquid lithium between 218° and 233°C.[49] Recent direct measurements,[130] having an estimated accuracy of ± 10%, have been made on 99·8% pure liquid lithium between 420° and 1002°F.: interpolated values together with an extrapolation to the melting point are given in Table IX.

On the basis of the Wiedemann-Franz-Lorentz law relating thermal and electrical conductivities, the thermal conductivity of liquid lithium at its melting point has been estimated as 0·085 to 0·11 g.-cal.sec.$^{-1}$cm.$^{-1}$°C.$^{-1}$ [131]

The thermal conductivity of lithium has been related to its specific heat

TABLE IX.- THERMAL CONDUCTIVITY OF LIQUID LITHIUM

Temp., °F.	354	400	500	600	700	800	900	1000
k, B.Th.U.hr.$^{-1}$ft.$^{-1}$°F.$^{-1}$	27	27	26	25	24	22	20	18

and the absolute temperature, and the lattice and atomic contributions to the thermal conductivity at 0°C. are given as 0·150 and 0·006 respectively.[132]

The heat-transfer properties of liquid lithium have recently been considered.[133]

Electrical Resistance

Bidwell[112] found the specific resistance of lithium at 0°C. to be 0·885 × 10^{-5}, and he combined this with his earlier measurements of relative resistance[18] to give the following values of electrical conductivity:-

t°C.	−250	−200	−150	−100	−50	0	20	50	100	150
Conductivity	1050	116	36·1	21·1	15·00	11·55	10·35	9·44	8·13	7·14

Other measurements of relative resistance have been made over the temperature ranges 20 to 373°K.,[128] 1·2 to 273°K.,[134] 1·8 to 273°K.[135,136] and 18 to 100°K.,[127a] MacDonald and Mendelssohn made continuous measurements in the temperature interval between 1·8 and 20°K. – normally a difficult range to cover experimentally.[135,136] Below about 4°K. the resistance was constant, and for the samples they employed the residual resistance had R/R_0°C. values of 3 to 5 × 10^{-3}. In Table X the values of resistance are corrected for the residual resistance. In dealing with the values of Meissner,[128] who only went down to 20°K., the residual resistance of Meissner and Voigt[134] is employed.

TABLE X.- RELATIVE ELECTRICAL RESISTANCE OF LITHIUM

Temp. °K.	R/R_0°C.

1·2	-	$0{\cdot}0000_5$	-

According to Meissner,[128] the slope of the resistance-temperature curve is nearly constant between 0 and 100°C. although it falls off below 0°C. Bidwell,[18] however, noted a slight break in the curve at about 50°C. as well as a considerable increase in resistance as the melting point is reached (Fig. I). Below 20°K., the resistance after subtracting the residual resistance is proportional to the temperature raised to the power 4·52.[135] Recent work has shown that lithium is not superconducting at temperatures down to 0·08°K.:[137,138] earlier work had shown that this was true down to 1·7°K.[139]

For most metals the electrical resistance decreases on application of pressure and increases under tension. Lithium shows an anomalous behaviour in that its resistivity increases under pressure.[140] This applies to both the solid and liquid states, the magnitude of the coefficient for the liquid being greater than for the solid:[141] the ratio of the resistance of solid and liquid lithium is little affected by pressure.[141] Bridgman[140] has extended his earlier measurements (Mellor,II,460) to higher pressures and has obtained the values for the effect of pressure on electrical resistance shown in Table XI.

TABLE XI. - EFFECT OF PRESSURE ON THE ELECTRICAL RESISTANCE OF LITHIUM

Pressure, kg./cm^2	0	2500	5000	10,000	15,000	20,000	25,000	30,000
R/R_0 30°C.	1·000	1·0175	1·0354	1·0727	1·1117	1·1524	1·1949	1·2394
75°C.	1·000	1·0172	1·0351	1·0730	1·1131	1·1553	1·1992	1·2453

Frank[142] has explained the abnormal positive pressure coefficient of resistance on the wave mechanical theory of the structure of lithium.

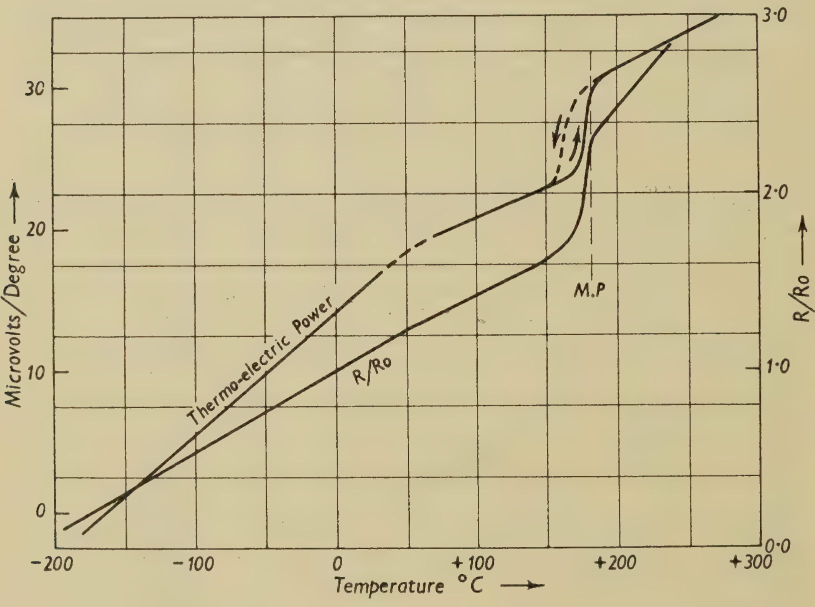

Fig. 1. VARIATION OF RELATIVE ELECTRICAL RESISTANCE AND THERMOELECTRIC POWER OF LITHIUM WITH TEMPERATURE

Although abnormal in having a positive pressure coefficient of resistance, lithium shows a normal behaviour towards tension.[66] The tension coefficient of resistance, *i.e.* the proportional change of resistance under a tension of 1 kg./cm.^{2}, is +4·8 × 10^{-5}. Using Richards[67] values of cubic compressibility, the tension coefficient of specific resistance has been calculated as +1·1 × 10^{-5}.[66]

A transverse magnetic field of 300 kilogauss increases the resistance of a lithium wire at room temperature by less than 2%; at 88°K. the same field results in a 15% increase.[143]

The electrical resistance of lithium vapour produced by electrically exploding a wire of the metal has been compared with that of other metal vapours produced in the same way: lithium vapour showed a lower resistance than the vapours of more noble metals such as copper, silver, gold, nickel, tungsten, zinc, aluminium and tin.[144]

Thermoelectric and Photoelectric Properties

The thermoelectric power of lithium has been measured relative to platinum over the range −180° to +285°C.[18] Interpolated values are:-

t, °C.	−150	−100	−50	0	+50	+100	+150	+200	+250
Microvolts per degree	+1·5	5·5	10	14	18	21	23	31·5	34

There is a change in the slope of the thermoelectric power–temperature curve at +50°C., and there is also a marked rise of about 6 microvolts per degree in the thermoelectric power as the melting point is approached (see Fig. I). Unlike that of the other alkali metals, the thermoelectric power of the liquid lithium continues to increase with rise of temperature. More recent work has given curves for the absolute thermoelectric force and absolute thermoelectric power of lithium between 6 and 50°K.[145] There is a sharp inflexion in the thermoelectric force–temperature curve at ~30°K.: the absolute thermoelectric power is positive.

A clean lithium surface has a very low photoelectric yield which is increased by the presence of impurity molecules.[146] This fact has been used as a criterion of purity. Photosensitive films of lithium have been prepared by the evaporation of solutions of lithium in ethylamine.[147] Ives and Olpin[148] have described the preparation of photosensitive films of lithium by distilling lithium on to a tungsten surface. As the films were formed they first became sensitive to blue light, then, as their thickness increased, to green, yellow and red light: on further increasing the thickness the red and yellow sensitivity disappeared and the final thick layer was sensitive only to blue light. The photoelectric long-wave limit for the thick films approached that previously given by Pohl and Pringsheim[149] (5200 A.) and by Millikan[150] (5260 A.) for lithium metal in bulk. The wave-length of maximum excursion of the photoelectric long-wave limit coincided with the first line of the principal series (6708 A.). Lithium films on platinum were much less sensitive than those on tungsten, and this has been attributed to alloying between the lithium and platinum.[148]

The spectral characteristics of lithium–antimony photocathodes have been studied[150a-d] and their sensitivity for light of colour temperature 2360°K. has been given as 5–20 μ amp.per lumen.[150a] Multipliers with a lithium–antimony surface are particularly advantageous in scintillation counters on account of their low thermionic emission (about one fiftieth of that for caesium–antimony).[150a]

Continuous absorption of light in lithium vapour for wave-lengths in the region of the series limit has been studied and the shape of the absorption curve investigated.[150e] The absorption cross section at the series limit has been given as 2·5 × 10^{-18}cm.^{2} with an uncertainty of ± 40%. On the short wave-length side of the series limit (from 2300 A. to 1850 A.) the absorption is approximately proportional to $\lambda^{3\cdot5}$: there is a fairly steep increase over a range of 5 A. on the long wave-length side of the limit to a maximum value at 2299·6 A.

Magnetic Properties

More recent determinations of the paramagnetic susceptibility of lithium have given values considerably higher than that of $0\cdot38 \times 10^{-6}$ quoted previously (Mellor,II,460). A measurement by the Gouy method gave a specific susceptibility of $3\cdot8 \times 10^{-6}$.[151] The Curie method has been used on thoroughly outgassed samples of lithium at field strengths from 4 to 7 kilogauss: by extrapolation to infinite field strength the effect of ferromagnetic impurities is eliminated and a susceptibility of $2\cdot6 \times 10^{-6}$ obtained.[152] Later measurements between 30° and 270°C. gave $2\cdot50 \times 10^{-6}$ at 30°C.: with increase of temperature the specific susceptibility rose slightly to $2\cdot57 \times 10^{-6}$ at the melting point, after which it dropped abruptly to $2\cdot42 \times 10^{-6}$ and then increased only slightly with further rise of temperature.[153] From other measurements between 13·9° and 300°K. the volume susceptibility (per c.c.) was represented by $\kappa \times 10^{-6} = 1\cdot90 + 7\cdot8/T$.[154] The major part of the temperature dependent term may, however, have been caused by dissolved iron present as an impurity. Computation of the volume susceptibility of lithium from a knowledge of the electronic structure has given $3\cdot32 \times 10^{-6}$ made up as follows:[155,156] spin paramagnetism, 3·54; free electron diamagnetism, −0·17; ion core diamagnetism, −0·05 (all $\times 10^{-6}$). The theoretical treatment indicates an increase in the paramagnetic susceptibility of pure lithium with decrease of temperature.

Electron spin resonance absorption has been observed in bulk and dispersed lithium.[156 a-f] Line widths and shapes, relaxation times and splitting factors (*g*-factors) have been determined. From electron spin resonance studies, that part of the volume susceptibility arising from polarization of conduction electron spins has been measured as $2\cdot0 \times 10^{-6} \pm 0\cdot3 \times 10^{-6}$ c.g.s. units.[156e] A theoretical spin susceptibility of $1\cdot87 \times 10^{-6}$ was calculated by Pines.[156g]

Numerous attempts have been made to evaluate the contribution of the lithium ion to the diamagnetism of its salts both from experimental data and from theoretical considerations. There are, however, wide divergencies among the recorded values, mainly as a result of differing treatments. Values given for the susceptibility of the lithium ion in solution from measurements on lithium salts include −4·0,[157] −3·3,[158] −2·9,[159] −1·6[160] and +0·3[161,162] (all $\times 10^{-6}$). Several wave-mechanical treatments have given a value about $-0\cdot7 \times 10^{-6}$ for the free lithium ion.[163-167] Other values for the free ion include −4·4,[158] −3·8[159] and −1·29[168] (all $\times 10^{-6}$). In a review of the field, Klemm[169] has given $+3\cdot0 \times 10^{-6}$ as the most probable value for the susceptibility of the Li^+ ion in solution, $-0\cdot6 \times 10^{-6}$ for the Li^+ ion in crystals and $-0\cdot7 \times 10^{-6}$ for the free ion. Another contemporary survey[170] recommends $-1\cdot0 \times 10^{-6}$ for the Li^+ ion but does not distinguish between the ion in solution and in crystals.[171] Several authors have reviewed methods of obtaining ionic susceptibilities and the values resulting from them.[169,170,172,173]

From the deflexion pattern which results when a beam of lithium atoms is passed through a non-homogeneous magnetic field (the Stern–Gerlach experiment) the magnetic moment of lithium is $9\cdot16 \times 10^{-2}$ gauss cm.[174,175] This corresponds very closely to one Bohr magneton. Measurements by the magnetic resonance absorption method have given the nuclear moment of ^{7}Li to be 1·165827 ± 0·000060 times that of the proton.[176,177] Taking the moment of the proton as 2·79 nuclear magnetons, this result agrees with other precise measurements of 3·25 to 3·26 nuclear magnetons for ^{7}Li.[178-180] Several other determinations have given values between 3·2 and 3·3 nuclear magnetons.[181-183]

Other aspects of the nuclear moment of ^{7}Li have been discussed by a number of authors.[187-202] Of several values for the magnetic moment of the ^{6}Li nucleus[178,179,203] the best is 0·8213 nuclear magnetons.[179] Quadrupole moments of lithium have been studied.[202b,202c,203a-g] The nuclear spin is 3/2 for ^{7}Li[179,181] and 1 for ^{6}Li.[179]

As with other metals, the nuclear magnetic resonance frequency of lithium in the metallic state is greater than in its non-metallic compounds.[184-186d] Knight[186a] gave the resonance shift $\Delta H/H$ at room temperature as $0{\cdot}02 \times 10^{-2}$. More recently the resonance shift for ^{7}Li has been given as $0{\cdot}0261 \times 10^{-2} \pm 0{\cdot}0002 \times 10^{-2}$ with respect to a liquid ammonia solution of lithium nitrate.[186b] The value was constant within the experimental error of $0{\cdot}0002 \times 10^{-2}$ between room temperature and 200°C. – a range which includes the melting point of lithium.[186c] Magnetic resonance absorption line shapes and widths have also been studied.[186b-d] Over a 50° temperature range centred at 255°K. the line width narrows with increasing temperature from 6·2 gauss to approximately 0·1 gauss.[186b]

Electrode Potentials

The investigations of Lewis and co-workers on alkali metal amalgams gave –2·957 V. for the standard electrode potential of lithium (on the hydrogen scale) in aqueous solution at 25°C.[204] From free energy data, a value of –3·045 V. is obtained for the same system.[205] This comparatively large discrepancy between the experimental and calculated values has not been accounted for.[205] Recent surveys[206,207] of electrode potentials have given the mean (3·01 V.) as the best value. Determinations of the alkali metal potentials from the decomposition potentials of their fused halides have included –2·091 V. for the potential of lithium extrapolated to 18°C.[208] A value of +0·8 V. for the absolute electrode potential of the lithium ion has been calculated from spectroscopic and thermodynamic data.[209]

The potential of the ionic double layer has been calculated for lithium as –0·69 V., from which a value of –2·33 V. has been given for the potential of zero charge (or of the maximum of the electrocapillary curve).[209a]

In various non-aqueous solvents the standard electrode potential of lithium is very little different from that in water. At 25°C. the standard potential of lithium in ethyl alcohol has been determined as –3·042 V.[210] and in methyl alcohol as –3·095 V.[211] In liquid ammonia at –50°C. the standard electrode potential is –2·99 V.[212,213] Other electrode potential measurements have been made in liquid ammonia,[214] *iso*amyl alcohol,[215] hydrazine[216] and anhydrous formic acid.[217] In Table XII the electrode potentials of the alkali metals in a number of non-aqueous solvents are compared using the data of Pleskov;[216,217] the potential of the rubidium electrode in each of the solvents is arbitrarily taken as zero.

TABLE XII.- ELECTRODE POTENTIALS IN NON-AQUEOUS SOLVENTS (RELATIVE TO Rb = 0 IN EACH SOLVENT)

Element		Solvent		
	NH_3 –50°C.	N_2H_4 25°C.	H.COOH 25°C.	H_2O 25°C.
Li	–0·31	–0·19	–0·03	–0·09
Na	+0·08	+0·18	+0·03	+0·22
K	–0·05	–0·01	+0·09	+0·01
Cs	–0·02	–	+0·01	–

Values for the electrode potential of lithium relative to that of other metals in various fused halide electrolytes have been obtained by direct measurement or by calculation from thermodynamic data.[217 a-b] Electrochemical series have been developed, the order of the metals varying with the temperature and with the nature of the anion.

The behaviour of lithium ions at the dropping mercury electrode has been investigated in both aqueous and non-aqueous media. Lithium was among elements studied by Heyrovsky[218,219] in his first polarographic experiments; he gave the deposition potential of lithium at mercury from aqueous solutions as -2·03 V. relative to a normal calomel electrode. Despite the very negative standard potential of lithium, its ions are discharged at a mercury electrode in neutral and alkaline solutions on account of (*a*) compound formation between lithium and mercury, and (*b*) the high hydrogen overvoltage at mercury. The negative potential does, however, limit the choice of supporting electrolyte; tetra-alkylammonium halides or hydroxides are virtually the only usable salts.[220] With tetramethylammonium chloride or hydroxide as the supporting electrolyte, the half-wave potential of lithium ions in aqueous solution at 25°C. has been given as –2·31 V.[221,222] and $-2{\cdot}38_5$ V.[222 a,222 b] relative to a normal calomel electrode. In 0·1 M-tetra-*n*-butylammonium hydroxide at 25°C. it has been given as –2·331 ± 0·003 V. against a saturated calomel electrode (equivalent to –2·3 V. against a normal calomel electrode).[222 c] The diffusion current of lithium in aqueous solution is, however, very ill-defined:[223] alcohol-water mixtures give better results. In 50% ethyl alcohol at 25°C., with 0·1 M-tetraethylammonium hydroxide as the supporting electrolyte, the half-wave potential of lithium is -2·31 V. relative to a saturated calomel electrode:[224,225] in 80% ethyl alcohol the potential is slightly less negative. The half-wave potential of lithium is sufficiently removed from those of the other alkali metals (Na, -2·07; K, -2·10; Rb, -1·99; Cs, -2·05; all in 50% ethyl alcohol +0·1 M-tetraethylammonium hydroxide) to permit separate determination of the lithium ion.[218] In liquid ammonia at -36°C. saturated with tetrabutylammonium iodide as supporting electrolyte, the half-wave potential of the lithium ion relative to a 0·1 N. $Pb/Pb(NO_3)_2$ reference electrode is -1·67 V.[226] Other polarographic studies have been made in methyl alcohol and in methyl alcohol-benzene and methyl alcohol-water solutions.[227]

Ionization Potentials, Electron Affinity and Electronegativity

Precise values for the three ionization potentials of lithium have been calculated from spectral series limits. Values, in electron volts, from two recent compilations are:-

I	II	III	Reference
5·39	75·62	122·42	228
5·40	75·7	121·8	229

Several other experimental methods[230-233] have been used to determine ionization potentials of lithium, and a number of theoretical treatments have been given.[23,24,27,234-240]

Estimates of the electron affinity of lithium obtained by quadratic extrapolation from the ionization potentials of isoelectronic species are 0·34,[241] 0·47[242] and 0·38 e.V.;[243] the last value is derived from the latest spectroscopic data. It has been suggested[242] that values obtained by such procedures are to be regarded as lower limits. A linear extrapolation method,[244] which in general yields less satisfactory values, gives 0·7 e.V. for the electron affinity of lithium.[243] Using a wave-mechanical variational method, Wu[245] calculated 0·54 e.V. for the electron affinity of lithium in its normal state.

More recently, a value of 0·74 e.V. has been calculated using the Ritz variational method in conjunction with an extrapolation procedure.[246] The positive electron affinity shows the negative Li^- ion to be stable. Such ions have been produced by bombarding nickel surfaces with Li^+ ions.[247]

On Pauling's electronegativity scale lithium has a value of 1·0, values for the other alkali metals being Na, 0·9; K, 0·8; Rb, 0·8 and Cs, 0·7.[33] Mulliken[248] has pointed out that the average of the first ionization potential and the electron affinity of an atom should give a measure of its electronegativity: the sum of the ionization potential and the electron affinity divided by 130 gives values in close agreement with Pauling's electronegativity both for lithium and other atoms.[33]

Miscellaneous Physical Properties

From nuclear magnetic resonance measurements[186d] the coefficient of self-diffusion in lithium has been given as:-

$$D(\text{cm.}^2/\text{sec.}) = 0{\cdot}24\,{}^{+\,0{\cdot}17}_{-\,0{\cdot}10}\,\exp(-13{,}200 \pm 400/RT)$$

Earlier nuclear magnetic resonance experiments[186b] led to 9·8 ± 1 kg.-cal./g. atom for the activation energy of self-diffusion whilst from the anomalous rise of electrical resistance that starts well below the melting point it has been estimated[248a,b] as 9·3 ± 0·35 kg.-cal./g. atom.

The coefficient of diffusion of lithium in mercury at 8 to 15°C. calculated[249] from the atomic radius and viscosity data using the Stokes–Einstein equation is 0·72 cm.^{2} per 24 hours. This is in reasonable agreement with the older experimental figure of 0·66 cm.^{2} per 24 hours (Mellor, II, 456).

Metallic lithium heated on the surface of germanium and silicon crystals diffuses rapidly into the crystals and acts as a strong donor element.[249a-c] Diffusion constants have been obtained by a method involving the measurement of *p-n* junction positions[249a] and also by measuring the mobility of the Li^+ ion and applying the Einstein relation between diffusion constant and mobility.[249b,c] The latter method which is considered to be capable of greater accuracy has given:[249c]

$$D(\text{cm.}^2/\text{sec.}) = 0{\cdot}0025\exp(-11{,}800/RT) \text{ for germanium } (150\text{–}600^\circ\text{C.})$$
$$\text{and } D(\text{cm.}^2/\text{sec.}) = 0{\cdot}0023\exp(-15{,}200/RT) \text{ for silicon } (360\text{–}860^\circ\text{C.})$$

When sealed tubes made of 1 mm. wall 0·1% carbon steel and containing lithium are heated in hydrogen it is reported that carbon inclusions in the steel are reduced by the hydrogen forming voids through which the lithium seeps out.[249d] Lithium does not permeate gamma steel or pure iron. Also quenched steels remain impermeable to lithium on heating at 600°C. in hydrogen because of the fine distribution of carbides.[249d]

Alkali halide crystals heated in contact with lithium vapour undergo additive colouration as they do with other alkali metals.[249e]

An approximate value of 3000 m./sec. has been obtained for the velocity of ultrasonic waves (12 Mc/sec.) in liquid lithium at 200°C.[249f]

Calculated values for the Hall coefficient of lithium, −0·00135[250] and −0·00137 c.g.s.,[251] are somewhat lower than an earlier experimental value (−0·0017 c.g.s.).[252]

Thin films of lithium, like those of the other alkali metals, are opaque to visible light but are highly transparent in the ultra-violet region of the spectrum.[252a,b] The wave-length at which an alkali metal ceases to exhibit the optical properties of a metal and acquires that of a transparent medium decreases with decreasing atomic number and for lithium lies between 1550 A.[252b] and 2050 A.[252a]

Refs. p. 50

The contact potential difference between lithium and barium surfaces, prepared by condensing their vapours on glass, has been measured as 0·03 ± 0·02 V., lithium being electropositive to barium.[253] This result has led to the value 2·49 ± 0·02 e.V. for the work function of lithium. Klein and Lange[254] have obtained the electron work functions of a large number of metals from potential measurements on amalgam systems: their values include 1·40 e.V. for lithium.

Lithium shows no natural radioactivity.[255]

PROPERTIES OF THE LITHIUM ION

Some properties of the lithium ion, and some properties that relate to both

Refs. p. 59

the metal and its ion, have been dealt with under the appropriate sections above. Other properties of the Li^+ ion will be considered here.

The Ion in Solution

The heat and free energy of formation of the aqueous lithium ion at 25°C. are −70·22 and −66·554 kg.-cal.g.ion^{-1} respectively.[1] Assuming equal values for the heat capacities of the NH_4^+ and Cl^- ions, the absolute heat capacity of the lithium ion at infinite dilution has been calculated as −9·9 g.-cal./degree/g.-ion.[1a] From thermal data for the ionization process Li_2CO_3 (solid) $\rightarrow$ $2Li^+$ (aq.) + $CO_3^{=}$ (aq.), Latimer *et al.*[2] obtained 4·7 ± 1·0 g.-cal.g.-ion^{-1} degree^{-1} for the entropy of the Li^+ ion (relative to that of the H^+ ion) in aqueous solution at 25°C. The Bureau of Standards selected value for the entropy of the aqueous lithium ion at 25°C. is 3·4 g.-cal.g.-ion^{-1} degree^{-1}.[1]

Kielland[3] used a variety of methods to calculate the effective diameter of the hydrated lithium ion, and then, taking a rounded value of 6×10^{-8} cm. for this dimension, used the Debye-Hückel theory to compute the activity coefficients of the lithium ion in aqueous solution at 25°C. shown in Table XIII.

TABLE XIII.- ACTIVITY COEFFICIENTS OF THE Li^+ ION IN AQUEOUS SOLUTION AT 25°C.

Total ionic concentration	0·001	0·002	0·005	0·01	0·02	0·05	0·1	0·2
Activity coefficient	0·975	0·965	0·948	0·929	0·907	0·87	0·835	0·80

The indefinite significance of ionic solvation numbers has been discussed by Bockris[4] who has distinguished between 'primary solvation' – where (*a*) the ion and its attached solvent molecules move as one entity during electrolytic transport, and (*b*) the solvent ions have completely lost their own separate translational degrees of freedom – and 'secondary solvation' which refers to all electrostatic interactions not included in the foregoing definition of primary solvation. Experimental methods which are believed to measure primary hydration numbers, viz. those employing ionic mobility, ionic entropy, compressibility and partial molar volume, give values of 5, 5, 3 and 2 respectively for the hydration of the lithium ion.[4] Using a dialysis method, it has been reported that five water molecules are bound to the Li^+ ion forming a complex aquo-metal ion and that a further ten water molecules are bound as water of hydration of the aquo-metal ion.[5] Samoilov[6] has criticized the concept of fixed ionic hydration numbers and definite Stokes' radii on the grounds that the time of stay of water molecules around ions is not markedly greater than in pure water. From viscosity and mobility data he has shown that even for the strongly hydrated lithium ion there can be no permanent binding of water since the time of stay of water molecules around the Li^+ ion is only twice that around molecules in a pure water medium. Solvation of lithium ions in such liquids as methyl and ethyl alcohol, acetone, acetonitrile and benzonitrile has been considered.[7] In water–alcohol mixtures the lithium ion is said to be solvated by alcohol pentahydrate molecules as well as by water and alcohol molecules.[8]

Independent treatments by Latimer and co-workers[9] and by Verwey[10] have led respectively to values of 121·2 and 120 kg.-cal.g.-ion^{-1} for the heat of hydration of the Li^+ ion, to 114·6 and 112·5 kg.-cal.g.-ion^{-1} for the free energy of hydration, and to 22 and 24·5 g.-cal.g.-ion^{-1} degree^{-1} for the entropy of hydration. In an earlier treatment, Bernal and Fowler[11] by two different methods calculated values of 136 and 131 kg.-cal.g.-ion^{-1} for the heat of hydration of the Li^+ ion. Whereas Bernal and Fowler assumed approximately equal heats of hydration for the equi-radial K^+ and F^- ions, Miscenko[11a] has ascribed equal heats of hydration to the Cs^+ and I^- ions on the grounds that the difference in their radii is compensated by the dipole moment assymetry in the water molecule. In this way he obtained 121 kg.-cal.g.-ion^{-1} for the heat of solvation of the Li^+ ion. Elsewhere, Miscenko[12] again using thermochemical data on the solvation of salts, has given the heat of solvation of the Li^+ ion in water as 125 kg.-cal.g.-ion^{-1} and in methyl and ethyl alcohols as 127 kg.-cal.g.-ion^{-1} From the Bjerrum equation for solvation, the same author calculates values of 240, 243 and 246 kg.-cal.g.-ion^{-1} for the heats of solvation of Li^+ in water, methyl alcohol and ethyl alcohol respectively; and from the Born equation for solvation he calculates 236, 231 and 229 kg.-cal.g.-ion^{-1} for the solvation energies in the same three solvents.[12] These calculations do, however, involve a number of dubious assumptions.[13]

A recent compilation[14] of ionic mobilities, using conductivity and transport number data from a number of sources, gives the values in Table XIV for the equivalent conductivity or mobility of the lithium ion at infinite dilution in water.

In heavy water at 25°C. the mobility of the lithium ion at infinite dilution is 30·93 and the transference number of the Li^+ ion in lithium chloride solution is reported to decrease by about 2% on passing from H_2O to D_2O.[15] In methyl alcohol the mobility of the lithium ion at infinite dilution is 39·82 at 25°C.,[16] while in ethyl alcohol it is 15·00 at 25°C. and 9·62 at 4°C.[17] Other values for ethyl alcohol–water mixtures at 25°C. are:-[13,18]

TABLE XIV.- MOBILITY OF THE LITHIUM ION AT INFINITE DILUTION IN WATER

Temp. °C.	0	5	15	18	25	35	45	55	100
λ_∞	19·4	$22{\cdot}7_6$	$30{\cdot}2_0$	32·8	$38{\cdot}6_8$	$48{\cdot}0_0$	$58{\cdot}0_4$	$68{\cdot}7_4$	115

Mol. % EtOH	5	10	15	20	30	40	60	80
λ_∞	26·7	19·9	16·7	15·2	14·0	13·8	14·7	15·8

A considerable amount of data exists for the conductivity of lithium salts in other non-aqueous solvents, but there is little corresponding transport number data to permit the calculation of precise ionic mobilities. Mobilities of the lithium ion in a wide range of non-aqueous solvents have, however, been obtained[7,19] with the aid of such relationships as that between conductivity and viscosity (Walden's rule). The heat of transport[20] and entropy of transport[21] for the Li^+ ion have been discussed.

Diffusion coefficients at infinite dilution may be obtained from the above mobility data by using the equation:[22] $D = 8{\cdot}93T \times 10^{-10}\,\lambda_\infty$ cm.^{2}sec.$^{-1}$. This leads to $1{\cdot}03 \times 10^{-5}$ cm.^{2}sec.$^{-1}$ for the diffusion coefficient of the lithium ion at infinite dilution in water at 25°C. The temperature dependence of the diffusion current of Li^+ ions at the dropping mercury electrode has been calculated.[23]

From measurements of the viscosity of mixed electrolytes in aqueous solution a value of 0·0087 has been calculated for the specific viscosity of the Li^+ ion in 0·1 N.solution.[24] Relationships between the viscosity, the mobility and the entropy of hydration of the lithium ion have been discussed.[25]

The extensive work of Okazaki on the Faraday effect in aqueous salt solutions has led to the following values for the magneto-rotatory power of the lithium ion (in min.cm.^{2}gauss^{-1}g.-ion^{-1}), a value of zero being assumed for the hydrogen ion:-[26]

Wave-Length, A.	5900	5500	5100	4700	4300	3900	3500
$[M]$	0·15	0·15	0·17	0·18	0·21	0·26	0·34

Okazaki[27] has also defined a molecular magnetorotation constant, $\Phi = Mnw\lambda^2/$

Refs. p. 59

$s(n^2 + 2)^2$, where n and w are respectively the refractive index and Verdet's constant for light of wave-length λ, M is the molecular weight and s the density: the constant is the sum of the Φ values for the constituent ions. For the lithium ion, Φ has a value of $-0{\cdot}68 \times 10^{-14}$: values for other ions include Na^+, $-0{\cdot}23$; K^+, $0{\cdot}61$; H^+, $-1{\cdot}41$; F^-, $1{\cdot}57$; Cl^-, $11{\cdot}17$; Br^-, $19{\cdot}58$.

The refractivity of the lithium ion in aqueous solution for the sodium *D*-line is –0·42.[28]

Exchange of lithium ions with other ions has been studied in a variety of synthetic ion-exchange resins[28a-q] as well as in natural exchangers such as minerals.[28r-w] Exchange systems to receive attention have included Li–H,[28f, 28j-p, 28r, 28u] Li–Na,[28m, 28v] Li–K,[28l-m] Li–Mg,[28s] and Li–Ag.[28n, 28v] The strength of binding of an ion by an exchanger depends on the charge of the ion and on its hydrated radius. For ions of equal charge the binding increases with decreasing hydrated radius, and in dilute solutions the adsorption affinities or exchange affinities of alkali metal ions follow the series $Cs^+ > Rb^+ > K^+ > Na^+ > Li^+$.[28a,c,r] Several specialist books may be consulted for further information on ion-exchange and its applications.[28x-z, 29]

The Gaseous Ion

Lithium ions can be produced by heating lithium compounds on a wire filament. A study of the emission from sources of various composition has indicated that the silicate $Li_2O,Al_2O_3,2SiO_2$ is the most satisfactory ion emitter.[30] The naturally occurring mineral spodumene, having a composition approximating to the above, has been used by a number of workers. An electron multiplier tube has been used for counting single lithium ions.[30]

Ionic microscopy has been carried out[30b-e] using lithium ions, and replacement of the electron source in an industrial electron microscope by a thermal Li^+ ion source has been described.[30d] Although theoretically Li^+ ions are capable of a higher resolving power than are electrons at the same accelerating voltage, the resolution in Li^+ ion images of oxide smokes obtained by Gauzit[30d] was lower than in electron images because of disturbing side effects and greater experimental difficulties. Lithium ions tend to destroy the object more than do electrons, and they can form deposits on it after a time.

At 0° and 298·16° K. the U.S. Bureau of Standards selected values for the heat of formation of the gaseous lithium ion are 160·799 and 162·860 kg.-cal. g.-ion^{-1} respectively.[1]

The mobility (in cm./sec./volt/cm.) of the Li^+ ion in various gases at 760 mm. and 20°C. is as follows:-[31]

He	Ne	A	Kr	Xe[32]	H	N
25·3	14·35	4·99	4·03	3·04	13·3	4·21

Other measurements[32] in helium, neon, argon and krypton are in fairly close agreement with the above. The temperature variation of the mobility in helium has been determined over the range 20·5 to 483°K.,[33] and mobility measurements have also been made in argon–xenon and helium-xenon mixtures.[34] A theoretical calculation employing the exchange force between lithium ions and helium has given 194 cm./sec./volt/cm. for the mobility of the Li^+ ion in helium.[35] In the presence of water vapour, alkali metal ions acquire a cluster of water molecules which reduces their mobility. The mobility of the Li^+ ion has been studied in all five of the rare gases containing small concentrations of water vapour, and the values are found to be about half those in the absence of water vapour.[32] In argon, krypton and xenon an upper limit of six has been assigned to the number of water molecules in an ion cluster, but the true number is probably less than this.

Measurements have also been made in pure water vapour.[36] Under conditions of low field/pressure ratio and low temperatures, all the inert gases may attach themselves to the Li^+ ion.[37] The number of attached inert gas atoms decreases with rise of temperature, and for a given temperature it increases along the series: He, Ne, A, Kr, Xe. Thus, in neon practically all the Li^+ ions show attachment at 90°K. but there is no attachment at 195°K. In argon the corresponding temperature limits are 195°K. and 290°K., while in xenon and krypton every ion collects at least one and probably two gas atoms at room temperature.

A good deal of work has been reported on the ionization of the inert gases by lithium and other alkali metal ions.[38-46] Beeck and Mouzon[41,42] found that, in general, an inert gas is most easily ionized by the alkali ion nearest to it in the periodic system. The potentials (ion velocities) required by Li^+ ions for them to ionize Ne, A, Kr and Xe were determined as 307, 100, 420 ± 10 and 250 V., respectively. Later work by Varney,[46] using a space-charge method sensitive to any resulting positive ions but not affected by secondary electrons liberated from the walls, revealed no ionization of the inert gases by Li^+ ions, and it has been suggested that the interference of secondary electrons may have been responsible for the results of Beeck and Mouzon. Scattering of lithium ions by metal vapours has been studied.[47,48]

Lithium ions can migrate through quartz plates in an electric field.[49,50] It is thought that migration takes place through tunnels inherent in the crystal structure and parallel to the principal axis of the quartz.[50,50a] Studies have also been made of the reflexion of lithium ions from metal surfaces.[51-54c] When the metals are given a coating of salts etc., the bombardment by lithium ions gives rise to negative ions.[53] Negative ions can also result from metal surfaces alone owing to the presence of adsorbed gases etc.[53] Negative lithium ions have been detected using such techniques.[55]

The ionic refractivity of the gaseous lithium ion for the sodium *D*-line is 0·20.[28] Values for the polarizability of the lithium ion include 0·075,[56] 0·0313[57] and 0·025[58] (all × 10^{-24}). Other dielectric parameters of the lithium ion have been evaluated.[59-61]

SOLUTIONS OF LITHIUM

Solutions of Lithium in Liquid Ammonia

Lithium dissolves readily and without reaction in liquid ammonia to give solutions which are blue when dilute. Concentrated solutions of alkali metals in ammonia show metallic reflexion, and according to Jaffe[1,2] the light reflected from a saturated solution of lithium in ammonia changes from deep red to yellow, green and finally white as the angle of incidence is increased from 0 to 90°. The absorption spectrum of the dilute solutions shows a single broad band with a maximum around 6700 cm.$^{-1}$ and a half-height width of about 3000 cm.$^{-1}$.[2a]

There is a slight increase of solubility with temperature from 10·698 g. of lithium per 100 g. of ammonia at −63·5°C. to 11·319 g. of lithium per 100 g. of ammonia at 0°C.[3] An earlier measurement at −39·4°C. gave 11·3 g. of lithium per 100 g. of ammonia.[4] All these solubility figures were obtained by studying vapour pressure-composition curves; an older direct determination gave a constant solubility of 10·3 g. of lithium per 100 g. of ammonia between −80° and 0°C.[5] The heat of solution becomes more negative with increasing lithium concentration and thus heat absorption occurs on dilution. When each lithium atom is dissolved in 102·8 moles of ammonia, the heat of solution is −79·6 kg.-cal. per atom of lithium: for one lithium atom in 20·9 moles of ammonia it is −8·38 kg.-cal.[6] Other measurements in dilute solutions have given −8·0[7] and −9·6 kg.-cal.[8] per g. atom of lithium. The high heat of solution has been attributed, in part, to the formation of an ammoniated metal ion.[6]

Density values for solutions of lithium in liquid ammonia at −33·2°C., are given in Table XV;[9] other determinations[10] at −35°C. are in close agreement with these ($d = 0·5435$ for 13·5 mole % Li to 0·4920 for 21·0 mole % Li).
For saturated solutions the density varies from 0·477 ± 0·006 at +19°C. to 0·495 ± 0·006 at −80°C.: the mean coefficient of expansion between −80° and +19°C. is 0·00036 ± 10%.[1] On solution there is an increase in the volume of

Refs. p. 64

TABLE XV. - DENSITY OF SOLUTIONS OF LITHIUM IN LIQUID AMMONIA AT −33·2°C.

Mole Fraction Li	0·0331	0·0571	0·0713	0·1180	0·1557	0·1616	0·1958	0·2105 (satd.)
Density	0·639	0·611	0·597	0·554	0·523	0·518	0·498	0·490

the system, and at high lithium concentrations the density of the solution is less than that of either of the consituents. At −35°C. the volume increase on solution varies linearly from 37·5 c.c. per g.-atom of lithium for a saturated solution to 41·4 c.c. for 1 g.-atom of lithium dissolved in 6·4 moles of ammonia.[10] A saturated solution of lithium in ammonia is the lightest liquid known at room temperature.[1]

Sound-velocity measurements have shown the adiabatic compressibility of concentrated solutions of lithium in ammonia to increase rapidly with increasing metal concentration.[10a] At 40 moles NH_3/g.-atom Li the compressibility was 55×10^{-12} cm.^{2}/dyne; at 10 moles NH_3/g.-atom Li it was 80×10^{-12} cm.^{2}/dyne.[10a]

Solutions of lithium in ammonia have a very low vapour pressure compared with that of the pure solvent. Representative values at −39·4°C. are shown in Table XVI.[4]

TABLE XVI. - VAPOUR PRESSURE OF SOLUTIONS OF LITHIUM IN AMMONIA AT −39·4°C.

Moles NH_3/Atom Li	1·72	3·40	4·07	4·88	5·79	7·56
Pressure, mm.Hg.	3·50	3·70	134·80	281·70	395·50	474·80
Moles NH_3/Atom Li	10·97	15·08	21·33	30·81	45·66	60·13
Pressure, mm.Hg.	520·30	534·10	538·70	543·60	539·70	549·60

Other measurements have been made at higher and lower temperatures.[3,11] For a saturated solution the vapour pressure reaches one atmosphere at about +63°C.[12]

The nature of lithium solutions in liquid ammonia has been the subject of much discussion and controversy. Early workers considered that alkali metals dissolve in liquid ammonia to give true compounds in which the metal is joined directly to the nitrogen atom of the ammonia forming a substituted ammonium radical,· and the term ‘metal ammonium’ was employed. But according to Kraus and Johnson,[4] while lithium atoms (or ions) may be associated with molecules of the solvent, there are no grounds for considering that in ammonia solutions there is a molecular complex resembling the ammonium group and they have condemned the term ‘metal ammonium’. The vapour pressure curve obtained by these workers was entirely regular with no indication of the irregularities observed by Benoit[11] from which the formation of a compound $Li,4NH_3$ or $Li_2,8NH_3$ had been deduced. A detailed review of work on the nature of alkali metal solutions in liquid ammonia with numerous references up to 1931 has been given by Johnson and Meyer.[13] Fernelius and Watt[14] have also reviewed the subject.

A study of the lithium-ammonia system below the freezing point of ammonia, −78°C., has shown a progressive depression of freezing point with increasing concentration of lithium, although there is a considerable departure from Raoult’s law.[15,16] At the eutectic temperature, −181 ± 3°C.,[1] −185°C.,[15,16] compound formation appears to occur, solvation of the lithium being carried over into the solid state to give a lithium ammoniate containing not more than 4 ammonia molecules for each lithium atom.[15-17] The solid is bronze-coloured and its low resistivity, 15×10^{-6} ohm cm., is a quarter of that for the saturated liquid phase.[1] Thin layers of the solid are blue by transmitted light.[16] A light absorption band at 1·15 μ has been observed in thin layers of ammonia containing small amounts of lithium, sodium or potassium at 20°K.[17a] This is independent of the nature of the alkali metal but there are further bands characteristic of the actual alkali metal employed; for lithium-ammonia layers at 20°K. an absorption band occurs at 585 mμ.[17a]

Dilute solutions of lithium in ammonia show an electrical conductivity behaviour similar to that of ordinary electrolytes, the equivalent conductivity approaching a limiting value with increasing dilution.[18] At a concentration of approximately 0·05 N. the equivalent conductance is a minimum (~450 ohms^{-1}) and thereafter it increases rapidly with increasing concentration (~900 ohms^{-1} at 0·5 N. and 125,000 ohms^{-1} at 2·3 N.). In concentrated solutions the electrical conduction is similar to that in metals.[1,18] At −80° the specific resistance of a saturated solution is 0·64 × 10^{-4} ohm cm.; the temperature coefficient of resistance between −80 and −120°C. is −0·02%.[1] According to Kraus[18,19] there exists in ammonia solutions the equilibrium $Li \rightleftharpoons Li^+ + e^-$, the positive carrier being the normal lithium ion while the negative carrier is the electron, which may be associated with one or more ammonia molecules. With increasing metal concentration the solvation of the electron decreases until eventually some carriers become free from ammonia molecules. It is the presence of these free electrons which is responsible for the metallic conduction at high concentrations. In dilute solutions, where the solvation of the electrons reduces their mobility, an appreciable part of the current is carried by the Li^+ ion, and the relative decrease in the number of carriers with increasing total lithium concentration results in a decrease in equivalent conductivity with increasing lithium concentration. While this theory gives a satisfactory account of the conductance behaviour it meets some difficulties in other directions.[20] More recently it has been proposed that the electrons are trapped in the solvent, there existing in the liquid cavities which serve to trap electrons singly or in pairs.[20a-c] Several other authors[2a,20d-h] have discussed and elaborated the model. A study of electrical conductivities and solubility relationships in the system lithium-sodium-ammonia[21] has shown that in dilute ammonia solutions the conductivities of lithium and sodium are practically additive.

A sharp rise in the resistivity of a solution containing ammonia and lithium in the ratio 15·5:1 when the temperature is lowered below −60°C. appears to indicate that separation into two phases occurs at this temperature.[22] At −70°C. two phases are clearly visible, the upper layer being bronze-coloured and the lower deep blue.

Photoelectric activity has been observed in solutions of lithium in liquid ammonia.[18] The Hall effect has been investigated in solid and liquid lithium-ammonia solutions.[1] The effect of a magnetic field on the electrical resistance of the solid has also been studied.[1]

The decomposition of ammonia solutions and the reactions of lithium dissolved in ammonia are discussed later (see page 87).

Other Solutions of Lithium

Solutions of lithium in solvents other than liquid ammonia have been given very little attention. This is doubtless due, at least in part, to their poor stability. Lithium is reported to be soluble in methylamine,[2a,23-27a] ethylamine[2a,28-29a] and ethylenediamine,[14,26] and to be slightly soluble in hydrazine.[30] The solutions are mostly blue and they deteriorate quite rapidly.[14,26,27] Two liquid phases have been reported in the lithium–ethylamine system at 0°C.;[29a] one is blue and the other colourless, the colourless phase being very slightly the denser. Lithium is insoluble in propylamine and in secondary and tertiary amines.[28] Solutions of lithium in methylamine (at −55°C.) and in ethylamine (at −40°C.) show broad light absorption bands at about 7600 cm.$^{-1}$ and 7000 cm.$^{-1}$ respectively.[2a] Paramagnetic resonance has been studied in solutions of lithium in methylamine and ethylenediamine.[26] Electrical conductance has been studied in concentrated solutions in methylamine.[27a]

A high solubility has been reported for lithium in its fused chloride although actual values of the solubility have not been determined.[31] The potential of a carbon electrode immersed in solutions of lithium in lithium chloride containing up to about 0·2% by weight of lithium has been studied at 650°C. and found to follow the equation[31] $E = \text{const.} - RT/F \ln [\text{Li}]$. The dissolved lithium is believed to exist in the atomic form or as the complex ion Li_2^+.

ATOMIC WEIGHT AND ISOTOPES

The internationally accepted value (1955) for the atomic weight of lithium remains at 6·940, a figure which was based originally on determinations of the LiCl:AgCl and LiCl:Ag ratios by Richards and Willard[1] in 1910. The only more recent chemical determination[2] of the atomic weight gave a value of 6·934 ± 0·001. This was obtained by determining the ratio LiCl:AgCl using pure lithium chloride prepared from the carbonate. A value of 6·9364 ± 0·0018 has recently been calculated from density and *X*-ray data and there is some reason for believing that this may be a more realistic figure than 6·940.[3] Urey and Greiff[4] pointed out in 1935 that isotopic exchange reactions can affect the atomic weight of lithium by about 0·001 and that atomic weights given to more significant figures are meaningless unless the isotopic composition is specified. Atomic weights calculated from the isotopic masses and the natural abundance ratio of the lithium isotopes vary considerably, mainly as a result of variations in the observed values of the latter (see below). Thus, while the most reliable mass spectrographic determinations of the abundance ratio have led to atomic weights of 6·939 to 6·943,[5,6] optical determinations of the abundance ratio have led to atomic weights around 6·90.[7-9]

Shortly after the first discovery of isotopes it was shown by several workers using the methods of positive ray analysis that lithium has two isotopes of mass number 6 and 7.[10-14] Since then numerous determinations of the natural abundance ratio of these isotopes have been made using both mass spectra and optical methods. It will be seen from Table XVII that there are wide variations – from 7 to 15 – in the reported values for the ^{7}Li/^{6}Li ratio, and that there are fairly consistent differences between the mass spectra and optical determinations. A recent survey of abundance ratio data for lithium showed no satisfactory explanation for the disagreement between the various workers.[15] The most widely accepted values lie between 12 and 13.

In measuring the abundance ratio using a mass spectrometer, Brewer[5,25] observed an isotope effect in the evaporation of lithium ions. A value of 11·6 was obtained for the ^{7}Li/^{6}Li ratio until the source – a platinum disc impregnated with a lithium compound – became 40% depleted. Beyond this point lower values were obtained, and after applying a correction for the isotope effect of free evaporation the ^{7}Li/^{6}Li ratio became 12·52. White and

Cameron[6] reduced the isotope effect of free evaporation by distilling the heavy molecule lithium aluminium chloride ($LiAlCl_4$) into the ionization region. Subsequent workers[5,18] have not supported a report[33] that the $^7Li/^6Li$ ratio decreases with increase of temperature. It has been reported[26] that the isotopic ratio in old mineral formations, presumed to be of marine plant origin, does not differ significantly from that in other sources. Cameron,[29a] however, has found small variations in the $^7Li/^6Li$ ratio of mineralogical and commercial samples of lithium compounds from various sources. In commercial samples of lithium salts the variation was between 12·44 and 12·93; in minerals it was between 12·47 and 12·72.

Mass spectroscopic evidence has been reported for the existence of ^5Li, with a $^7Li/^5Li$ ratio of 20,000±1000.[24] Later work has not, however, confirmed the existence of such a stable isotope, and lower limits of 10^5 and 10^7 have been given for the $^7Li/^5Li$ ratio.[6,34]

In addition to the stable isotopes ^6Li and ^7Li, other artificial lithium isotopes with short half lives have been produced in nuclear bombardment reactions. A recent review,[35] which also summarizes methods of production and disintegration schemes, lists ^8Li with a half life of 0·88 sec. and ^9Li with a half life of 0·17 sec. There is also a metastable excited state of ^7Li which decays by undergoing an isomeric transition and has a half life of $5{\cdot}2 \times 10^{-14}$ sec.

The earliest measurements of the precise masses of the lithium isotopes were made by Aston,[36,37] and by Costa,[38,39] who showed that they lay close to whole numbers. In 1933 Bainbridge,[40] from mass spectrographic measurements, obtained $^6Li = 6{\cdot}0145 \pm 0{\cdot}0003$ and $^7Li = 7{\cdot}0146 \pm 0{\cdot}0006$ on the physical basis of atomic weights ($^{16}O = 16$). Other calculations of the isotopic masses of lithium have been made from measurements of nuclear reaction energies. These include (all on the physical scale) $^6Li = 6{\cdot}0143 \pm 0{\cdot}0002$, $^7Li = 7{\cdot}0148 \pm 0{\cdot}0002$;[41] $^6Li = 6{\cdot}01634$, $^7Li = 7{\cdot}01720$;[42] $^6Li = 6{\cdot}0170$, $^7Li = 7{\cdot}0182$;[43] $^6Li = 6{\cdot}0167$, $^7Li = 7{\cdot}0180$;[44] $^6Li = 6{\cdot}01670 \pm 0{\cdot}00012$, $^7Li = 7{\cdot}01799 \pm 0{\cdot}00011$;[45] $^6Li = 6{\cdot}01682 \pm 0{\cdot}00011$, $^7Li = 7{\cdot}01784 \pm 0{\cdot}00009$.[46] Bainbridge[47] in 1948 recommended the adoption of $^6Li = 6{\cdot}01690$ as the most probable value from mass spectrograph and nuclear disintegration experiments: ^7Li was given as $7{\cdot}01820 \pm 0{\cdot}00010$ from mass spectrograph values only. A survey[47a] based on mass spectrographic and nuclear reaction data available up to 1952 has given $^6Li = 6{\cdot}017028 \pm 0{\cdot}000006$ and $^7Li = 7{\cdot}018225 \pm 0{\cdot}000007$; a more recent survey by Drummond[47b] has given virtually the same values.

From measurements of the isotope effect in the red region of the Li_2 absorption spectrum, Almy and Irwin[48,49] obtained a value of $1{\cdot}04077 \pm 0{\cdot}0004$ for the mass coefficient, ρ. The mass coefficient is related to the relative masses of the lithium isotopes (the mass ratio) by the expression: mass ratio $= 2\rho^2 - 1$, and this leads to a value of $1{\cdot}16640 \pm 0{\cdot}00016$ for the mass ratio $^7Li/^6Li$. Another determination[32] also using the red absorption bands of lithium is in excellent agreement with the above ($\rho = 1{\cdot}04076 \pm 0{\cdot}0003$; mass ratio $= 1{\cdot}16636 \pm 0{\cdot}00009$), and these values also agree closely with those obtained from mass spectrometric measurements[39,40] and from nuclear transformation energies.[41-46] Earlier measurements in the blue-green region of the Li_2 absorption spectrum gave higher values of $1{\cdot}04141 \pm 0{\cdot}00008$ and $1{\cdot}1690 \pm 0{\cdot}0003$ for the mass coefficient and mass ratio respectively.[50,51]

Separation of Isotopes

The only complete separations of the lithium isotopes have been performed on a comparatively small scale by employing the principle of the mass spectrograph.[17,52-55] Using as a source platinum filament coated with a mixture of the composition $3Li_2CO_3,Al_2O_3,3SiO_2$, Oliphant, Shire and Crowther[52] passed a beam of positive lithium ions through crossed electric and magnetic fields to collect 5×10^{-8} g. quantities of ^{6}Li and ^{7}Li on two small metal targets placed slightly apart. Collection of this quantity took 50 minutes for ^{6}Li and 5 minutes for ^{7}Li. The pure isotopes were fixed by admitting a little hydrogen chloride to form lithium chloride. Smythe and co-workers,[53] using a high intensity mass spectrometer with a Kunsman catalyst as source, achieved a higher ion current and collected several 10^{-6} g. samples of ^{6}Li and ^{7}Li. In their instrument the peaks for the two isotopes were separated in space by about 3 cm. Production-scale mass spectrographs, originally developed to enrich uranium-235, have recently been used for the separation of the lithium isotopes at ion currents up to several milliamperes.[55] With such currents lithium may be resolved into its isotopes at rates of the order of 0·1 g. per hour. Lithium chloride with a few per cent. of lithium metal is the charge material, and it is vaporized into the ionization chamber. The lithium metal is added to eliminate practical difficulties which are otherwise caused by dissociation of lithium chloride into $LiCl^+$, Li^+ and Cl^+. The large percentage mass difference between ^{6}Li and ^{7}Li permits the attainment of high isotopic purities.

Yatabe and Stedman,[56] following a detailed literature survey, considered methods of separating the lithium isotopes from the viewpoint of possible production in large quantities. The methods considered most suitable for successful separation of ^{6}Li and ^{7}Li were:-

1. distillation of lithium and its compounds;
2. liquid phase partition of lithium and its compounds;
3. chromatographic methods;
4. electro-migration methods;
5. combined chromatographic and electro-migration methods.

According to Bell,[57] separation of ^{6}Li and ^{7}Li by electrolysis would probably be less efficient than by other methods. Calculation of equilibrium data for the exchange reaction $^6LiH + {}^7Li \rightleftharpoons {}^7LiH + {}^6Li$ has led to an enrichment factor of 1·028 at 273°K., 1·025 at 298°K. and 1·008 at 600°K.[4] Lewis and MacDonald[58] changed the ^{7}Li/^{6}Li ratio from 11·6 to 5·1 by passing lithium amalgam through an 18 metre long column of lithium chloride in absolute alcohol or of lithium bromide in alcohol and dioxan. The lighter isotope accumulated at the foot of the column. Isotopic enrichment of lithium has also been reported by thermal diffusion in aqueous media,[59,60] by ion exchange,[61-64 a] by electrolysis of aqueous solutions of lithium salts using a mercury cathode,[62-66] by electrolysis of fused lithium nitrate,[67] by electro-migration in fused chlorides[68] and by partial precipitation of lithium as carbonate[29 a,69] and phosphate.[29 a] Attempts to separate the isotopes by an electrogravitational method were unsuccessful.[70]

SECTION IV

THE CHEMICAL PROPERTIES OF LITHIUM

By MRS. F. DICKINSON

Within the last two decades a good deal of interest has been centred on the chemistry of lithium since its production on a commercial scale is relatively recent, although the element has been known for more than a hundred years. Much of the early work on lithium has been repeated; further reactions, including those in liquid ammonia, have been studied; the application of the metal in the field of organic chemistry has been extended, and the alloying properties of lithium in examined some detail. This intensive study is reflected in the numerous additions made to the literature in the period now reviewed.

Lithium occupies the first position in Group I of the Periodic Table and, although in many ways a typical alkali metal, in some respects it closely resembles its neighbouring elements, magnesium and calcium in Group II. It is less reactive than the other alkali metals with water, oxygen and the halogens and more reactive with nitrogen, carbon and hydrogen. Its halides have a relatively high solubility in water while its carbonate and hydroxide are less soluble than those of sodium and potassium. The differences between lithium and the other alkali metals is partly explained by the fact that its ionic potential is greater and approaches the larger potentials of the alkaline earth ions.[1-3]

A freshly cut surface of lithium has a silvery appearance; on exposure to air the surface becomes dull and the corrosion products formed in the first five minutes have been shown by an electron diffraction study to be undoubtedly lithium oxide and lithium hydroxide. From the thermal data:-

$$Li + H_2O \rightarrow LiOH + 0{\cdot}5H_2 + 53{\cdot}2 \text{ kg.-cal.}$$
$$Li_2O + H_2O \rightarrow 2LiOH + 22{\cdot}3 \text{ kg.-cal.,}$$

it is apparent that, with respect to water, lithium is in a higher energy state than lithium oxide and that lithium hydroxide is likely to be formed directly from the metal. On the other hand, the abundant supply of oxygen in the air may cause the oxide to be formed first. In a short exposure the carbon dioxide in the air has no effect on the metal, but on prolonged exposure, a soft, white deposit of lithium hydroxide and carbonate is formed.[4-7] The kinetics of the corrosive action of water vapour have also been studied. The black, glassy coating first formed persists for a time, dependent on the temperature and pressure of the water vapour, and then changes to a white material. Analysis of both the black and the white coating by an X-ray diffraction method shows that the only compound present is lithium hydroxide, but the black material is characterized by broad peaks and absence of some reflections, which suggests that a completely crystalline hydroxide is not formed during the early stages of the reaction. By observing the evolution of hydrogen as a function of time for several water vapour concentrations, the reaction, studied between 45° and 75°C., has been shown to proceed according to a logarithmic rate law: $W = k \log (1 + at)$, where W is the extent of reaction in time t and k and a are constants. The rate constant is independent of the water vapour pressure over a range of 22 to 55 mm. and the energy of activation for the reaction is found to be 6·2 to 5·5 kg.-cal./mol. depending on the pressure of the water vapour.[8] When lithium is stored in tins which are not quite air-tight, so that the air entering is largely freed from carbon dioxide and water vapour, a dense, brittle, reddish-brown material is formed which is believed to be lithium nitride.[2]

Lithium metal can be cut in air without danger of fire but its reactivity increases rapidly as the temperature approaches the melting point. Liquid lithium is readily ignited and once alight is difficult to extinguish because it reacts with most gases, with soda-ash and sand, with asbestos, concrete and asphalt, with carbon tetrachloride and in fact with almost all substances except metals, powdered graphite and zirconium silicate. The last two substances are those generally used to extinguish liquid lithium fires.[2,9,10] Although lithium salts give an intense carmine-red flame test, lithium itself burns, like magnesium, with a dazzling white flame.[11] The relative value of lithium as a rocket fuel has been considered and its ϕ value (*i.e.* the number of kg.-cal. per g. of a mixture of the fuel with the amount of oxygen required for complete combustion) compared with those of 33 possible gaseous and liquid organic compounds. These values vary from a minimum of 1·32 for acetaldehyde to a maximum of 3·21 for hydrogen, while the value for lithium is 4·72. Since, however, it is a solid up to 186°C., fuel tanks and lines containing lithium would have to be heated.[12]

A cost comparison has been made of high-energy rocket propellants including lithium, liquid ozone, liquid fluorine, chlorine trifluoride, fluorine monoxide, nitrogen tetroxide, liquid hydrogen, atomic hydrogen, liquid ammonia, hydrazine, liquid methane and beryllium. Liquid oxygen is likely to remain the cheapest oxidant but may meet competition from nitrogen tetroxide and liquid ozone.[13] Factors limiting the possible performance of rocket motors using chemical propellants have been discussed by Neat[14] and the mixture ratio, exhaust velocities for an expansion ratio of 50 and 250 *in vacuo*, combustion temperature and mean specific gravities of the mixtures are given for a number of known propellants, including a mixture of lithium and oxygen. Although a 1·2:1 mixture of oxygen to lithium has a higher bulk density than the liquefied gases cited, it appears doubtful that it will find extensive use because of the high molecular weight of the combustion products. Also, high exhaust velocities can be obtained only at the expense of high temperatures.

When lithium is burnt in excess of oxygen the monoxide, Li_2O, is formed and the dense white smoke produced is extremely irritating and obnoxious.[2] Despite the higher heat of vaporization and the higher ionic potential of lithium, the heat of formation of its oxide is considerably higher than that of any other alkali metal oxide. This is probably explained by the fact that the radii of the lithium and oxygen ions are small enough for them to approach closer than is possible, say, in the formation of cæsium oxide, and since the heat set free is inversely proportional to the square of the distance between the ions it is not surprising that the heat of formation of lithium oxide is relatively high.[1] The vapour pressures of lithium monoxide have been measured by an effusion method over the temperature range 1532° to 1669°K. and the equilibrium constant, K, calculated for the reaction:-

$$Li_2O_{(s)} = 2Li_{(g)} + 0{\cdot}5O_{2(g)}.$$

When $-\log K$ is plotted against $1/T$ the experimental points are mostly above the curve obtained by calculation from the heat of formation of the oxide from its gaseous elements and the free energy functions. In view of the somewhat high experimental results as well as the theoretical calculations of the stability of the oxides, Li_2O and LiO, it seems possible that the vapour of lithium monoxide may contain at least one of the gaseous oxides in concentrations comparable to those of the gaseous elements.[14] The peroxide is not formed in any quantity by the combustion of lithium, because it is thermally unstable and begins to lose its oxygen at 250° C. When oxygen is passed through liquid ammonia solutions of lithium, the initial blue colour of the solutions is destroyed and a white product, consisting chiefly of the monoxide with about 23% of the peroxide, is isolated on removal of the solvent.[16] Lithium does not dissolve readily at −78° C. in liquid ammonia but it may be oxidized at this temperature. If the metal is oxidized as it is added there is no initial blue colour, but instead a bright lemon yellow solution is obtained owing to the formation of a superoxide of lithium. If the temperature is allowed to rise to −33° C., the yellow colour fades and a white suspension forms; the colour changes cannot be reversed by cooling again to −78° C. Whether the metal is oxidized at −33° C. or −78° C. or whether the oxidation is effected in the presence or absence of excess metal, the white flaky product left on evaporation of the solvent is always the same, consisting of the monoxide with about 26% of the peroxide and about 5% of nitrite.[17] Lithium amalgam, 0·1%, reacts with oxygen when vigorously stirred at room temperature to give a 30% yield of lithium peroxide. This low yield may be due to a side-reaction by which the peroxide in the presence of excess lithium is converted into lithium oxide.[18]

When a lithium solution in ethyl alcohol is treated with hydrogen peroxide, lithium hydroperoxide monohydrate is formed. This compound, to which earlier workers[16,19] assigned the formula $Li_2O_2,H_2O_2,3H_2O$, has now been shown by analysis and *X*-ray powder diffraction studies to be LiO_2H,H_2O (Li_2O_2, $2H_2O$).[20] Solubility investigations of the ternary system, $LiOH–H_2O_2–H_2O$, at 10°, 0°, −10° and −21° C. reveal the solid phases, $Li_2O_2,H_2O_2,3H_2O$, Li_2O_2, $H_2O_2,2H_2O$ and $Li_2O_2,2H_2O$.[21] When the compounds, $Li_2O_2,H_2O_2,2H_2O$ and $Li_2O_2,2H_2O$ are heated to 150°–170° C., hydrogen peroxide and water are lost simultaneously and Li_2O_2 remains. This conversion gives a basis for ascribing the perhydrate composition, and not LiO_2H,H_2O, to the compounds.[22]

In the cold, lithium reacts slowly with water forming the strong base lithium hydroxide and hydrogen; at elevated temperatures the reaction is much more vigorous and enough heat may be generated to ignite the hydrogen.[2] Lithium hydroxide monohydrate, $LiOH,H_2O$, is produced when lithium, in the form of metal ribbon, is added to distilled water and the moist product, obtained by partial dehydration with phosphorus pentoxide at 20 mm. pressure and 25° C., is allowed to attain equilibrium with anhydrous lithium hydroxide.[20]

The intense blue-coloured solutions of the alkali and alkaline earth metals in liquid ammonia have been shown to contain the ordinary metal cations and ammoniated electrons[23] and it has long been supposed that similarly coloured solutions would be formed in water were it not that the metals react readily with the solvent. It has now been shown that when lithium is packed into a piece of glass tubing of small diameter and brought into contact with water, a blue line at the reacting surface is frequently visible.[24] The idea that the alkali metals may be physically soluble in water greatly affects the point of view adopted towards such processes as reduction by metal amalgams and the solution of the metals in acids.[25] The separation of hydrogen isotopes by displacement reactions of metals with water, acids or bases has been effected by several workers.[26-30] The metal is dissolved in the reagent of known deuterium content and the evolved hydrogen burned in a flame with a slight excess of oxygen. The proportion of the hydrogen isotopes in the water so formed is determined by density measurements. According to Johnston and Davies[30] the data are reproducible and confirm the applicability of the relationship, $d \ln [H] = \alpha\, d \ln [D]$ in which [H] and [D] are instantaneous values of the amounts of protium and deuterium in the liquid phase and α the "isotopic separation factor". For lithium and water at about 30°C. the above authors obtain a value for α of 1·84–1·86; for lithium and water and lithium and aqueous sulphuric acid Hughes, Ingold and Wilson[29] give values for α of 1·49 at about 40°C.

The heat of hydrolysis, corrected to infinite dilution and 25°C. for the reaction, $Li(s) + H_2O(l) = LiOH\ (\infty) + 0{\cdot}5H_2(g)$, is −53·10 ± 0·11 kg.-cal. per g.mol.[31]

Lithium combines with hydrogen at 680–700°C. at a rate such that 1·5 c.c. of the gas reacts with one sq. cm. of the metal per second.[32] Hydride formation begins before the metal is fused and the smooth reaction is probably due to the high solubility of the metal in the hydride.[33] The reaction has also been carried out by allowing hydrogen to react with freshly distilled lithium obtained by heating an intimate mixture of a lithium compound with a reducing metal, preferably aluminium, at a sufficiently high temperature to reduce the compound and distil the resulting metal.[34] In connexion with the synthesis of ammonia from metallic hydrides and nitrides, the rate of formation of lithium hydride has been studied between 400° and 525°C., and it has been found that the reaction proceeds comparatively slowly at 500° to 525°C., the metal absorbing about 118 times its volume of hydrogen in 30 minutes. Metallic promoters, particularly manganese and nickel in the proportions of 1:1, markedly increase the absorption of hydrogen by lithium. At higher temperatures and at pressures below atmospheric lithium sublimes freely.[35] Hurd and Moore[36] obtained a value of 44,000 ± 2,000 g.-cal. for the heat of the reaction:-

$$2LiH = 2Li + H_2$$

by plotting their experimental values of log p against $1/T$ over the temperature range of 509–653°C. Guntz and Benoit,[37] by calorimetric measurements, found a value of 43,600 g.-cal. The heat of formation of lithium hydride has been calculated from the difference between the heats of reaction of the hydride and the metal with water, measured by carrying out the reaction in a specially designed bomb enclosed in an adiabatic calorimeter jacket. The value obtained for LiH is −21·34 ± 0·09 kg.-cal. per mole.[38,39] A later publication gives −21·34 ± 0·15 kg.-cal. per mole.[31] The stability of the alkali and alkaline earth hydrides decreases in the order Li, Ca, Sr, Ba, Na, K and this is another example of the close relationship of lithium with the alkaline earth metals. The melting point of lithium hydride is 680°, and at 640° the vapour pressure does not exceed 70 mm. of mercury.[33] It is worthy of note that the first instance of hydrogen appearing as a negatively charged ion was established when lithium hydride was electrolyzed; the hydride is regarded as a salt and the relationship of hydrogen to the halogen family is further demonstrated by the similarity of the atomic arrangement in LiH and NaCl.[1,38] From a calculation of the energy of interaction of lithium ions with hydrogen, using the Heitler–London method, it has been concluded that a stable system cannot be formed.[40] Perturbation theory has been applied to calculate the effect of the hydrogen atom at the bonding distance from lithium. The H_{mn} terms[a] for the systems, H_{1s1s} and H_{1s2s} and H_{1s2p} are $-3{\cdot}87 \times 10^{-3}$, $-5{\cdot}69 \times 10^{-4}$ and $-1{\cdot}50 \times 10^{-3}$ respectively (a, 1 atomic unit = 27·205 eV).[41]

The binary systems of lithium with mercury have been investigated and heating and cooling curves prepared for sixty-seven alloys. The lithium–mercury system, as constructed from these data, comprises: $LiHg_3$ (0·6–18% Li), $LiHg_2$ (18–29% Li), solid solutions of LiHg (29–70% Li), Li_2Hg (70–72%

Li), Li_3Hg (72–91% Li), Li_6Hg (91–92% Li), solid solutions of Li (92–100% Li). There is a eutectic point at −42°C., corresponding to 0·6% Li, and another at 160°C. with 92% Li; the compounds Li_3Hg, m.p. 375°C., and LiHg, m.p. 590°C., fuse without decomposition, and the upper limits of existence for the other compounds are 164°C. for Li_6Hg, 375°C. for Li_2Hg, 340°C. for $LiHg_2$ and 235°C. for $LiHg_3$.[42] *X*-Ray analysis gives results in agreement with the thermo-analytical data.[43] Lithium amalgam reacts with carbon dioxide to form the oxalate, and the presence of small amounts of water or oxygen results in the formation of considerable amounts of carbonate. It has been shown by thermodynamic calculations that lithium amalgam can reduce carbon dioxide to carbon monoxide.[44–46] According to Henglein and Sontheimer,[45] yields of 0·1 and 4·5% of lithium oxalate are obtained at 20°C. and 250°C. respectively and small amounts of other complex substances as well as carbonate are formed. The yield of oxalate from metal amalgams is related to the half-wave potential of the amalgams. The presence of carbonate is explained by the following equations:-

$$2Li + CO_2 = Li_2O + CO;\quad Li_2O + CO_2 = Li_2CO_3.$$

Hohn, Fitzer and Nedwed[47] detected no carbon monoxide in the reaction products and no by-products when moisture and oxygen were rigidly excluded. They obtained 1·38 g. *i.e.* a 62·2% yield of lithium oxalate in 83 minutes from a 0·032% lithium amalgam at room temperature.

At high temperatures lithium combines readily with the halogens to form the corresponding halides. The energies of combination of the gaseous metal ions with gaseous halogen ions to form solid halides have been calculated from the best available thermochemical and spectroscopic data and it has been found that for the larger alkali metal and halogen ions the values are all about 165 kg.-cal. For the smaller ions the energy of combination increases, becoming 235 kg.-cal. for lithium fluoride. This probably accounts for the fact that the compounds formed from elements of low atomic number are highly stable compared with what would be expected from such electrochemical criteria as the 'replacement series'.[48] The 'standard state' heat of formation per g. equivalent of crystalline lithium chloride, *i.e.* the heat of formation of the compound from its elements in the standard state divided by the valency, plotted against the logarithm of the product of the atomic numbers of the elements, falls on the straight line obtained for the chlorides of the other alkali metals. Since a linear plot is also obtained for the chlorides of the alkaline earth metals, for those of boron, aluminium, scandium, yttrium and lanthanum and for the chlorides of carbon, silicon, titanium and zirconium, both along the groups and periods, an unknown $-H$ value may be safely predicted by interpolation or extrapolation, provided that the elements are in the standard state.[49]

The chemiluminescence exhibited when iodine reacts with lithium in the vapour phase has been examined spectroscopically. The first lines of the principal series of lithium are present and faint; apparently continuous bands are also seen, but the lines are more diffuse than would be expected from the pressure, which never exceeded 15 mm. The available energy data are not sufficient to explain these results.[50]

Chemical reactions between lithium and water, acids and caustic alkalies have been investigated, the reaction velocity being plotted against log $[H^+]$, taking that with water as 100. Graphs are given for hydrochloric, sulphuric, nitric, acetic and boric acids and for caustic soda solutions, and it is concluded that the observed effects are the combined result of the reactions: $2H^+ + Li \rightarrow H_2 + 2Li^+$ and $2H_2O + 2Li \rightarrow H_2 + 2OH^-$. The reaction which continues when the $[H^+]$ is below the concentration in dilute acid is that producing hydrogen gas directly from the water molecule.[51]

Sulphur vapour reacts with heated lithium to give a yellowish amorphous powder of lithium sulphide,[52] Li_2S, but according to later workers[53,54] the colouration is due to oxidation on exposure to air. The reaction between the elements, when either is molten, is very violent; even under an organic liquid serious decomposition of the liquid occurs and the product is contaminated with carbon and metallic carbide. The following example is given: lithium, 1 g., is melted under 150 ml. of boiling naphthalene and sulphur is added through a reflux condenser in 0·5 g. portions. No reaction occurs until 0·5 g.-atom has been added when a reaction starts with explosive violence. Further quantities of sulphur do not appear to react. The material is filtered from the liquid naphthalene, thoroughly washed with boiling toluene and strongly heated in a vacuum to expel residual solvent. On treatment with water, hydrogen and hydrocarbons are evolved from free metal and carbides and free carbon is deposited. Analysis shows that the main product of the reaction is lithium monosulphide and that the polysulphide is present only in minute amounts.[55] Sulphur reacts very vigorously with solutions of lithium in liquid ammonia at −33°C., producing initially a slightly soluble, white, amorphous precipitate of the monosulphide, Li_2S. Further reaction with sulphur leads to the formation of a light yellow or orange disulphide, and this in turn reacts with more sulphur giving a tetrasulphide which is readily soluble in liquid ammonia forming an intense orange-yellow solution. The reactions may be represented thus: $2Li + S \rightarrow Li_2S$; $Li_2S + S \rightarrow Li_2S_2$; $Li_2S_2 + 2S \rightarrow Li_2S_4$; $Li_2S_4 + (n{-}4)\,S \rightarrow Li_2S_n$. After removal of the solvent, the polysulphide is separated from unchanged sulphur by the action of water vapour. The sulphides containing four or more atoms of sulphur retain several molecular proportions of ammonia when dried *in vacuo* at 20°C. but the tetrasulphide loses nearly all the ammonia when heated at 140°C. under reduced pressure. The monosulphide has been isolated as a white powder which rapidly becomes coloured on exposure to air.[53,54] The heat of formation of Li_2S is 57·5 kg.-cal./mole equiv. according to Osborg[1] but more recently Juza and Uphoff have given a value of 106·5 kg.-cal. per g.-mol. for the reaction: $2Li_s + S_{rh} = Li_2S_s$.[56]

Selenium, like sulphur, reacts very readily with lithium dissolved in liquid ammonia at −33°C. Initially a white, sparingly soluble and apparently amorphous precipitate of the monoselenide, Li_2Se, is formed. The reaction occurs within five to twenty minutes, the time varying inversely as the concentration of the lithium in solution. With excess of selenium the soluble diselenide, Li_2Se_2, is first formed, further reaction producing very soluble polyselenides the formation of which is accompanied by an intense colour change. Usually it takes one to two days to establish equilibrium between the polyselenide solutions and selenium, and the average composition of the selenide then appears to be $Li_2Se_{5.4}$. It is believed that this substance is a mixture of Li_2Se_4 and a higher polyselenide, perhaps Li_2Se_6. The monoselenide is isolated as a white ammine and when heated at 150°C. in a vacuum it changes to a reddish-brown ammonia-free salt. The selenides are readily oxidized in moist air with the separation of selenium.[53,54,57]

Lithium and tellurium react together in liquid ammonia solution forming a white product, Li_2Te, which rapidly becomes coloured on exposure to air.[54]

When hydrogen sulphide is passed into ether to which lithium metal has been added, hydrogen is liberated at the surface of the metal and a white precipitate collects at the bottom of the container; the reaction is complete in about twenty-four hours and the product, which is free from polysulphides, has been shown to be lithium hydrogen sulphide, LiHS. This compound readily combines with alcohol forming the alcoholate, $2LiHS,C_2H_5OH$.[58] When the alcoholate is heated very rapidly to 360°C. in an evacuated vessel, a faintly yellowish-brown product containing approximately 55·6% of the monosulphide is obtained; the remainder is lithium ethoxide. On passing hydrogen, with about 10% of hydrogen sulphide, over the material at 120°C., the ethoxide is reconverted to lithium hydrosulphide and alcohol distils over. When the mass is heated to 360° in the presence of phosphoric oxide and solid potassium hydroxide, nearly pure lithium monosulphide is produced together with a very small quantity of polysulphide. When an alcoholic solution of lithium hydrosulphide is boiled with excess of sulphur in a current of dry hydrogen, hydrogen sulphide is rapidly evolved and the solution becomes dark red. The only polysulphide obtained is the disulphide, $Li_2S_2C_2H_5OH$.[59]

Lithium reacts with alcohol to form lithium ethoxide as a suspension. On treatment with hydrogen sulphide, the ethoxide is converted into lithium hydrosulphide, LiHS, and on removal of excess of hydrogen sulphide, by boiling in a stream of nitrogen, and addition of an equivalent amount of lithium ethoxide to the colourless solution, lithium monosulphide, Li_2S, is formed. The action of sulphur on aqueous, aqueous-alcoholic, and anhydrous alcoholic solutions of lithium monosulphide give polysulphide solutions from which crystalline products cannot be isolated. Alcoholic solutions of lithium hydrosulphide, with various proportions of sulphur, yield lithium tetrasulphide, Li_2S_4, and on crystallization at room temperature, the composition of the crystals corresponds to the formula, $Li_2S_4,2C_2H_5OH$. With less sulphur, mixtures of tetrasulphide and unchanged hydrosulphide are obtained. Higher polysulphides may be formed but cannot be isolated by crystallization. At the boiling point of the solutions only an alcoholated disulphide, Li_2S_2,C_2H_5OH, can be separated. The disulphide is far more stable than the tetrasulphide.[55] Lithium hydrogen sulphide is also formed by the action of hydrogen sulphide on lithium amylate. It is sensitive to air and decomposes at about 50°C. The enthalpy of formation of lithium hydrosulphide from its elements is −60·0 kg.-cal. per g.-mol.[60]

It is believed that the alkali-metal hyposulphites have not been successfully prepared by direct action between an alkali metal and sulphur dioxide. When, however, the alkali metal is in the form of an addition product with certain ethers, the hyposulphites can be conveniently prepared in good yield by treating the reaction products with sulphur dioxide. In the case of lithium, the metal–ether addition product is best prepared by using the metal in the solid state. At temperatures above the melting point of lithium there is some tendency for the metal to split the ether. The ether may be ethylene glycol dimethyl ether but other ethers of polyhydric alcohols may be used (see also Sect. XXV)[61]

At high temperatures lithium reacts with gaseous ammonia giving lithium amide, $LiNH_2$, and hydrogen. The same products are obtained when lithium solutions in liquid ammonia are allowed to stand in the presence of metal catalysts. The reaction takes about eight days when the solution, in a sealed tube containing platinum gauze, is exposed to light.[62-64] Benoit attributes the increase in rate of reaction which he observed to the presence of impurities, probably potassium, in the lithium metal.[65] Iron wire has also been used as a catalyst.[66] The amide is a white crystalline substance and its heat of formation is 42 kg.-cal./mol.[64]

The reaction of lithium with ammonia to give the amide is slower than the corresponding reaction of cæsium, and the same difference is observed in the reaction with methylamine; the heavier is the alkali metal the quicker is the reaction. The blue solution of lithium in methylamine, when heated in a sealed vessel at 50–60°C., decomposes to a white powder which is almost insoluble in methylamine: $Li + CH_3NH_2 \rightarrow CH_3NHLi + \frac{1}{2}H_2$. The methyl-amide decomposes still further on heating to give the imide: $2CH_3NHLi \rightarrow CH_3NLi_2 + CH_3NH_2$; and cautious thermal decomposition in a high vacuum gives a mixture of the imide and cyanide.[67]

At room temperature, lithium reacts very slowly with nitrogen forming lithium nitride, Li_3N; the speed of the reaction increases greatly as the temperature approaches the melting point of the metal.[2] In connexion with the formation of metallic hydrides and nitrides and their significance in the synthesis of ammonia, the activation energy of adsorption of nitrogen on lithium has been evaluated at 47 kg.-cal. per mole. An investigation of the rate of reaction between nitrogen and lithium has been carried out at 400–500°C. and the velocity constants have been determined between these temperatures. The metal absorbs about 300 times its own volume of the gas, in conformity with the formula Li_3N. The nitride is a dark grey solid which absorbs moisture rapidly from the air, liberating ammonia. Metallic promoters have little appreciable effect on the absorption of nitrogen by lithium, but of those tested cæsium is the best.[35] A small quantity of nitride, but no azide, is formed when nitrogen activated by an electric discharge reacts with lithium; in this respect lithium differs from the other alkali metals which give azides.[68] The electrolysis of an alcoholic solution of lithium chloride in a cell placed in a hermetically sealed chamber filled with nitrogen at a pressure of 1000 atm. yields lithium nitride as an intermediate product in the preparation of ammonia: $Li_3N + 3C_2H_5OH \rightarrow 3LiOC_2H_5 + NH_3$.[69] Nitrogen is removed from combustible gases by bringing the mixtures into contact with a lithium amalgam to form lithium nitride, Li_3N. The lithium nitride–mercury mixture from the scrubbing vessel is treated with water to produce ammonia and lithium hydroxide from which lithium may be recovered by electrolysis in the presence of mercury or a fusible alloy, preferably used as a liquid cathode. The process is particularly suitable for removal of nitrogen from natural gas.[70]

Phosphorus combines with lithium at 680°C. to give a reddish-brown mass of lithium phosphide, Li_3P. A brownish-black compound, Li_3As, is formed when lithium and arsenic are heated together at 800°C. Juza and Schulz[71] state that the reactions between lithium and phosphorus, and lithium and arsenic, in an argon atmosphere, are so violent that the phosphorus and arsenic should be added in small portions at a time. The arsenide is also obtained as a fine brown powder by adding a solution of lithium in liquid ammonia to a suspension of powdered arsenic in the same liquid, and under similar conditions antimony yields the blue-grey antimonide, Li_3Sb. The reaction between red phosphorus and lithium in liquid ammonia does not go to completion.[72] Phosphine reacts readily with lithium in liquid ammonia solution with the formation of lithium dihydrogen phosphide and the liberation of hydrogen. At 0°C. the tetra-ammoniate of this compound may be isolated, but on raising the temperature it is thermally decomposed to the di- and mono-ammoniate. The last molecule of ammonia cannot be removed without the loss of 0·5 mole of phosphine per mole of phosphide, and the final product obtained by heating to 50°C. is dilithium hydrogen phosphide, Li_2PH.[73] A similar reaction occurs when arsine in passed into a liquid ammonia solution of lithium. At −70°C. the metal solution is rapidly decolorized, hydrogen is evolved and the ammoniate, $LiAsH_2,4NH_3$, is formed; on warming up to 0°C. in a vacuum, ammonia is given off leaving the diammoniate which may be further decomposed by heating to 70°C. to dilithium hydrogen arsenide, Li_2AsH, and finally to lithium arsenide, Li_2As. No further change occurs on heating to 450°C.[74]

Lithium reacts rapidly but quietly with liquid dinitrogen tetroxide yielding the insoluble nitrate, free from nitrite, and nitric oxide.[75] A radical-like salt is formed when lithium is added to sodium nitrite in liquid ammonia; the compound, $LiNaNO_2$, which is regarded as a salt of the unknown 'hydronitrous' acid, H_2NO_2, is very reactive towards moisture, air and carbon dioxide and decomposes violently at 100–130° C.[76]

Boron does not react directly with lithium. Boric acid in alcoholic solution when added to lithium in absolute alcohol gives a white crystalline precipitate of lithium borate, Li_2O, B_2O_3.[77] Metallic borohydrides are excellent reducing agents, providing efficient sources of hydrogen, and may be used for production of diborane and related boranes. The following typical reactions occur: $4Li + 2H_2 + BF_3 = LiBH_4 + 3LiF$; $4Li + 2H_2 + B(OCH_3)_3 = LiBH_4 + 3LiOCH_3$; $6Li + 3H_2 + 2BF_3 = B_2H_6 + 6LiF$.[78]

Elemental boron in a high-density crystalline form is prepared by a continuous process in which boron trifluoride in the gaseous form is caused to react with a gaseous dispersion of an alkali metal. The example cited is: $BF_3 + 3Na \rightarrow B + 3NaF$, but other alkali metals may be used.[79] According to Moissan,[80] deep blue, small, lustrous crystals of lithium silicide, Li_6Si_2, are obtained when lithium and silicon are heated at 400–500° C. in a vacuum; the excess of lithium metal is removed by distillation at a temperature not exceeding 600° C. because above that temperature the silicide decomposes giving off lithium vapour and leaving amorphous silicon as the residue. More recently Osborg[81,82] has shown that it is possible to prepare a number of 'alloys' of lithium and silicon by heating the elements together at temperatures above 600° C. in an evacuated container. The 'alloys' are solid, hard, uniform masses of metallic appearance having the compositions and properties given in Table I.

TABLE I.- PROPERTIES OF 'ALLOYS' OF LITHIUM WITH SILICON

Composition % Li	% Si	Density	Freezing Range °C.	Author
60	40	About 1·0	500–550	Osborg[81]
50	50	1·17	About 625	Osborg[81]
40	60	1·4	680–700	Osborg[81]
25	75	1·72	700–750	Osborg[81]
Li_6Si_2 42·3	57·5	1·12	Decomposes above 500	Moissan[60]

Klemm and Struck have found that when lithium–silicon mixtures in the ratios of Li : Si <2 : 1 or >4 : 1 are heated under argon in nickel crucibles to temperatures not exceeding 650° C., part of the silicon or lithium is unaffected. A 2 : 1 mixture, tempered at about 530° C., is a dark blue-violet substance; a 4 : 1 mixture tempered at about 630° C., is a silver-grey substance. Chemical analyses and *X*-ray examinations agree with the formulae Li_2Si for the blue and Li_4Si for the grey compound. Under other conditions, products of indeterminate colour, or two separable phases, are obtained. The existence of Moissan's compound, Li_3Si, has not been confirmed.[83]

The solubility of lithium in silicon has been determined by measuring the change in resistivity upon saturation at a series of temperatures between 450° and 1000° C.; the results are given in the form of a solubility curve.[84] Reiss and Fuller[85] from theoretical considerations of ionization and solubility in semi-conductors, constructed a solubility curve which agreed with experimental data with the exception of the point at 500° C. which was considered to be in error. Pell[86] has also measured the solubility of lithium in silicon between 600° and 1400° C., and found that at higher temperatures it is not possible to quench rapidly enough to prevent serious precipitation, as revealed by comparing electrical measurements of lithium remaining in solution after cooling with chemical measurements of total lithium content. Total lithium content has, therefore, been determined by flame analysis and the resulting solubility agrees with previous electrical measurements[87] at 600°C. but departs markedly from them at higher temperatures and in general follows the curve predicted from thermodynamic principles.[88] Reiss and Fuller[89] have since analyzed the specimens used in their electrical measurements and agree now with the results obtained by Pell.

Lithium combines with carbon at a red heat to give lithium carbide; with sugar charcoal reaction occurs with incandescence; with graphite and diamond there is no incandescence: $2C \text{ (diamond)} + 2Li \text{ (solid)} \rightarrow Li_2C_2 \text{ (solid)} + 11{\cdot}3$ g.-cal. In preparing the carbide it is necessary to use a double tube, one of porcelain inside a glass tube, because lithium vapour attacks the porcelain and may cause it to fracture; and the reaction should be carried out in a vacuum for at a red heat lithium absorbs most gases. The temperature should be raised slowly as the lithium carbide formed will otherwise decompose very rapidly to lithium and carbon; prolonged heating has the same effect. Lithium carbide is also formed when carbon is heated with substances which dissociate to give lithium; lithium hydride and lithium nitride for example will thus give lithium carbide, and in the latter case lithium cyanide is also produced. Carbon cannot be used as an electrode in the electrolysis of fused lithium chloride because the lithium carbide formed at the temperature of electrolysis diffuses into the chloride mass and is there decomposed giving carbon which remains in suspension in the liquid.

Compounds containing carbon are also decomposed when heated with lithium; carbon monoxide forms lithium carbide when passed over lithium at red heat. If a stream of carbon dioxide is passed over heated lithium, at a rate slow enough to prevent the temperature rising above red heat, lithium carbide is obtained, but if the temperature is allowed to rise higher only a small amount of carbide is formed. If lithium is gently warmed in pure ethylene the metal is at first covered with a white incrustation; if the temperature is then raised to about 700°C. the coating melts and the lithium becomes incandescent because of the heat evolved in the absorption of ethylene. A molten greyish-white product is obtained with no deposition of carbon, and analysis shows it to have the composition $C_2H_4Li_6$. The product is probably a mixture of lithium carbide and lithium hydride, for on treatment with water acetylene, hydrogen and lithium hydroxide are formed: $C_2H_4 + 6Li \rightarrow Li_2C_2 + 4LiH$; $Li_2C_2 + 4LiH + 6H_2O \rightarrow C_2H_2 + 4H_2 + 6LiOH$. Metallic lithium is an active promoter in ethylene polymerization. Mixtures of alkali metals and oxides of Group 6A of the periodic table (chromium, molybdenum, tungsten or uranium) are used as catalysts for the polymerization of ethylene, propylene or their mixtures to produce solid polymers of high molecular weight. The reaction is carried out at 130°–260° and 1000 lb. per sq.in. pressure in a liquid medium. Benzene, toluene or xylenes are preferred media for the polymerization of ethylene, and *cyclo*hexane, decalin or *iso*-octane for the polymerization of propane. The alkali metals alone are not catalysts; it might be assumed that they function by reacting with catalyst poisons which might be present in small proportions of the order of a few p.p.m. When no alkali metal is present, a subhexavalent Group 6A metal oxide is required as catalyst but with an alkali metal present the catalyst can be a Group 6A solid oxide in the form of a trioxide. The proportion of alkali metal can be varied from 0·001 to about 2 parts by weight per part by weight of the metal oxide catalyst. Many different types of supports for the catalyst, including γ-alumina, can be used when alkali metals are present. The promoting activity of the metal increases with increasing atomic weight.[90] When lithium is warmed slowly in an iron vessel in a stream of acetylene an abundant deposit of carbon is obtained with the formation of some acetylide and hydride. If the metal is heated under reduced pressure and acetylene is passed briskly over the lithium, heat is evolved and lithium carbide and hydride are obtained: $C_2H_2 + 4Li \rightarrow Li_2C_2 + 2LiH$. In this case there is only a slight deposit of carbon.[91-93] It has been suggested that fused salts containing metal ions should catalyze reactions that are normally brought about by the corresponding metals in the free state and lithium chloride, like lithium, causes the pyrogenic decomposition of acetylene at 600°C.[94] Liquid ammonia solutions of lithium react with acetylene to give lithium acetylide, $LiHC_2$, which is stable and free from carbide as long as it remains in solution; attempts to isolate it, however, by removal of the solvent result in spontaneous decomposition to the carbide and the product is a mixture of 82% of lithium carbide and 17·6% of the acetylide.[95] Lithium reacts with trifluoromethyl hypofluorite, CF_3OF, to give carbonyl fluoride and lithium fluoride: $2Li + CF_3OF = 2LiF + COF_2$. The reaction is slow at room temperature; over a period of hours the original lustrous metal surface is completely tarnished and carbonyl fluoride formed, but much of the hypofluorite remains unchanged. When the glass reaction vessel is heated to a temperature near the melting point of lithium, a strong reaction occurs with the liberation of enough energy to melt the glass. This reaction is accompanied by the intense carmine-red light characteristic of lithium.[96]

Gaseous hydrogen cyanide passed over lithium at 570°C. in the absence of air yields a grey product which when freed from excess of metal contains 35·8% of lithium cyanide and 43·2% of lithium cyanamide. A 20% solution of hydrogen cyanide in anhydrous ether reacts immediately with lithium forming a white precipitate which after washing with ether and drying in vacuo at 100°C. is found to contain 84% of lithium cyanide. A similar reaction occurs when a 50% solution of hydrogen cyanide in benzene is used and if the reaction is carried out quickly the product contains 99% of lithium cyanide. To obtain pure lithium cyanide it is essential to use rigorously dried materials.[97,98] At temperatures not higher than 300°C., cyanogen forms lithium cyanide and paracyanogen, $(CN)_6$, when the gas is led into an iron vessel containing lithium, but above this temperature appreciable quantities of lithium cyanamide are produced: for example, when a temperature of 400°C. was reached over a period of six hours the product contained 20% of lithium cyanide and 29·2% of lithium cyanamide, the remainder being paracyanogen. The suggested mechanisms for the reactions are: $2Li + (CN)_2 \rightarrow 2LiCN$; $2Li + (CN)_2 \rightarrow Li_2NCN + C$; or $2LiCN \rightarrow Li_2NCN + C$.[97] The formation of lithium cyanamide in various reactions, however, indicates that it is a transformation product of lithium cyanide.[99]

In its behaviour towards constructional metals and alloys lithium is found to be more difficult to contain than sodium (see Sect. XXV). Austenitic steels, nickel-base alloys, manganese and cobalt-base alloys, and copper and copper alloys all show a poor resistance to molten lithium. Vanadium, beryllium and chromium are severely attacked. Mild steel may be used to store or melt lithium. 'Armco-iron' is efficient up to 600°C., stainless steel to 500°C., and low-carbon steels to 700°C., while columbium, tantalum and molybdenum resist attack up to 1000°C. Zirconium and titanium show a fair resistance to attack.[2,100-102] The leaching of nickel from the surface of 304 stainless steel by the action of molten lithium at 1000°C. is described by Brasunas[103] and photomicrographs are given. Bar graphs giving temperatures below which systems may be operated with lithium for 1000 hr. with less than 0·005 in. attack on iron, low-alloy steel, ferritic stainless steel, austenitic stainless steel, nickel, 'inconel,' cobalt, 'stellite,' copper, copper-base alloys, refractory metals (molybdenum, niobium, tantalum, zirconium, titanium, tungsten and vanadium) and precious metals, silver, gold and platinum are given both for static and dynamic systems. Lithium nitride, Li_3N, is the most harmful contaminant when working with lithium. No satisfactory material has been found to handle lithium in dynamic systems above 1200° F. Below 1000° F., the stainless steels give good resistance.[104; 105]

The heats of reduction of twenty five oxides of metals and metalloids by lithium and by thirteen other elements have been calculated in order to compare them with the normal electromotive potentials of the elements: there appears to be a parallelism between the heats of reduction and the potentials indicating that the thermal reduction processes are ionic reactions.[106] Oxides or oxygen-containing compounds with uranium in the acid radical are reduced by fused lithium or alloys of lithium with sodium or potassium, with or without carbon or magnesium. Gases such as oxygen, nitrogen, hydrogen or carbon dioxide must not be present. In the following reaction: $U_3O_8 + 16Li = 3U + 8Li_2O$, 813 g. of the oxide and 132 g. of lithium, *i.e.* 25 g. excess of lithium, are heated together in argon. The initial temperature is 390° C., the maximum temperature, 985°C. Lithium oxide and excess of lithium are leached from the reaction products with water, hydrochloric acid is added to the solution to bring the pH down to about 6 and the resulting lithium chloride solution is evaporated to dryness, mixed with potassium chloride, fused and electrolyzed to produce lithium metal which may be used again. Alloys of uranium may be produced by reducing a uranium compound mixed with a compound such as the oxide of the desired alloying constituent. Instead of lithium, alloys such as lithium-sodium, lithium-potassium or lithium-sodium-potassium may be used.[107]

Titanium oxide is reduced to titanium by heating with lithium: 80 g. of lithium (25 g. excess) in the form of three slabs 2·5 × 2 × 0·75 in. is placed in a steel pan and loosely surrounded on all sides with 160 g. of finely powdered titanium oxide, TiO_2. The pan is placed in a low-carbon steel retort, the head is bolted to the end of the retort, the air evacuated and argon introduced. The charge is heated and the initial reaction sets in at 200–400° C., depending upon the grade and quantity of the charge. The reaction is indicated by a flash of light and a rapid temperature increase to a maximum of 700–900° C. The temperature then falls to about 600° C. and is brought up to 675° C. and maintained there for about 0·5 hr. The retort and charge are allowed to cool to room temperature, the reaction products are removed from the retort in the container and placed in water. After leaching out lithium monoxide, Li_2O, and excess lithium, the finely divided titanium metal is removed by filtration, thoroughly washed and dried. The solution of lithium hydroxide is treated with hydrochloric acid, evaporated to dryness, mixed with potassium chloride, fused and electrolyzed to recover lithium metal for recycling: $TiO_2 + 4Li = Ti + 2Li_2O$; $Li_2O + H_2O = 2LiOH$; $2Li + 2H_2O = 2LiOH + H_2$; $LiOH + HCl = LiCl + H_2O$. When the charge of lithium metal is four times as large, the maximum reaction temperature exceeds 1400° C. The following reactions are carried out in a similar manner: lithium titanate, 110 g., lithium, 70 g., excess lithium, 42 g., initial temperature of reaction, 475° C., maximum temperature, 790° C.: $Li_2TiO_3 + 4Li = Ti + 3Li_2O$. Vanadium pentoxide, 67 g., lithium, 32 g., excess lithium, 6 g., initial temperature of reaction 394° C., maximum temperature, 768° C.; $V_2O_5 + 10Li = 2V + 5Li_2O$. Niobium pentoxide (87·8% Nb_2O_5), 20 g., lithium, 10 g., excess lithium, 5 g., initial temperature of reaction is 320° C., maximum temperature, 490° C., $Nb_2O_5 + 10Li = 2Nb + 5Li_2O$. Tantalum pentoxide, 72 g., lithium, 7 g., initial temperature of reaction 410° C., maximum temperature 595° C. $Ta_2O_5 + 10Li = 2Ta + 5Li_2O$. The source of tantalum pentoxide is an ore containing a high percentage of the pentoxide. Chromium oxide, 200 g., lithium, 70 g., excess lithium 16 g., initial temperature of reaction about 180° C., maximum, 965° C. $Cr_2O_3 + 6Li = 2Cr + 3Li_2O$. Molybdenum oxide, 194 g., lithium, 70 g., excess lithium, 14 g., initial temperature of reaction 180°C., maximum temperature >1400°C. $MoO_3 + 6Li = Mo + 3Li_2O$. Tungsten oxide, 153 g., lithium, 37 g., excess lithium, 10 g., initial temperature of reaction 200°C., maximum 1030°C. $WO_3 + 6Li = W + 3Li_2O$. Manganese telluride, 170 g., lithium, 20 g., excess lithium, 7 g., initial temperature of reaction 230°C., maximum temperature, 660°C., $MnTe + 2Li = M + Li_2Te$. Iron sulphide, 240 g., lithium, 10 g., excess lithium, 15 g., initial temperature of reaction 260°C., maximum temperature 945°C. $FeS + 2Li = Fe + Li_2S$. The metals, magnesium, calcium, barium and cerium cannot be obtained in the pure state by the above method but are produced as lithium alloys.[108]

It is more difficult to displace lithium from its salts by reaction with other metals than it is to effect a similar reaction with salts of the other alkali metals, and this is believed to be due to the higher heats of formation of lithium salts and the higher boiling point of lithium; thus, the fluoride and chloride of lithium can be heated with iron in a vacuum at 1000°C. without any reaction occurring[109] (see page 6). Cerium trifluoride is reduced by lithium to cerium: $CeF_3 + 3Li \rightarrow Ce + 3LiF$. The heat of reaction is 27 kg.-cal./g.-mol. of CeF_3 at 400°C. In order to obtain the best possible separation between cerium and flux, the reaction products and the remainder of the reactants should be melted during the course of the reaction. There is small likelihood of the reactants reaching a temperature at which they will all be molten solely as a result of the heat of reaction, but the deficiency can be met either by heating the reactor externally after the reaction is complete, or by boosting the reaction with an additional simultaneous reaction. In the first case contact between the molten cerium metal and the walls of the reactor will be prolonged and the risk of contamination of the cerium thereby increased. In the second case a suitable booster reaction is that between lithium and iodine which liberates 66·43 kg.-cal./g.-mol. of lithium iodide. The reactor is constructed of mild steel tubing, 1·75 in. internal diameter by 10 S.W.G. wall, the bottom, flange and lid being made from 0·25 in. mild steel plate. A gasket of 16 S.W.G. copper wire is used between the flange and lid and is satisfactory although not gas-tight. Molybdenum has been found to be the best lining material and the lining consists of a molybdenum can 4·5 in. high by 1·5 in. diameter. The reactants are pressed into pellets only slightly smaller in diameter than the inside of the can, and loaded into the can which is then placed on a bed of calcium fluoride in the reactor. A disc of molybdenum is placed on top of the can and more loose calcium fluoride added for heat insulation. There is a small space all around the outside of the can permitting free radiation from the inner wall of the reactor. If iodine is absent from the charge the reactor is evacuated and filled three times with argon; if iodine is used the above practice is abandoned because the vapour pressure of iodine is too high at room temperature.

The loaded reactor is sealed and placed in a 'Kanthal'-wound pot furnace heated to at least 1300°C. After about 15 min. the temperature of the outside wall of the reactor is about 1100°C. and this temperature is maintained for a further 30 min. by adjusting the furnace temperature. The reactor is removed from the furnace, allowed to cool, and the can is taken out of the reactor and opened up down its length. Cerium is at the bottom, the flux on top, cleanly separated from it, and excess lithium on top of this. A certain amount of cerium is always present on the inside walls of the molybdenum can throughout its whole height. Consistently high yields of cerium are obtained by this procedure with efficiencies up to 82·5%. The lithium–cerium fluoride reaction is apparently initiated at about 600°C., the lithium–iodine reaction at 200°C., and although the latter apparently contributes no useful heat to the system it appears to reduce the melting point and increase the fluidity of the slag. A typical charge for the reactor is: 110 g. cerium trifluoride, 20 g. iodine, 14·1 g. lithium (11·7 g. to react with cerium fluoride, 1·1 g. to react with iodine and 10% excess). This is compacted into five or six pellets each containing the same proportion of reactants, packed in layers to give the closest approximation to intimate mixing. The molybdenum can adheres so strongly to the cerium button that it has to be filed off it. If, however, a $^1/_{32}$-inch layer of cerium immediately below the can is also removed, molybdenum contamination is negligible. Small quantities of occluded flux can be easily removed by remelting in ceria crucibles in a vacuum better than 0·0001 mm. Hg. Metal of 99·92 to 99·93% purity is consistently made.

A similar reaction has been carried out by using cerium trichloride in place of the trifluoride but the reaction is not nearly so successful because although cerium is produced it does not coalesce but remains finely dispersed throughout the reaction cake. Increasing the high temperature soaking time and the temperature has no beneficial effect on the coalescence of the metal. The failure of the process is almost certainly due to the presence of a tenacious skin of the oxide or oxychloride on the surface of the metal. An oxide film is probably formed in the fluoride reaction but the fluoride flux dissolves it and keeps the metal surface clean. The cerium chloride–lithium reaction appeared to be initiated at a similar temperature to that at which the fluoride reaction occurred, but with a considerably greater liberation of heat: $CeCl_3 + 3Li \rightarrow 3LiCl + Ce + 44{\cdot}0$ kg.-cal./g.-mol. of $CeCl_3$ at 400° C.[110]

Mixtures of lithium and organic halogen compounds are sensitive to impact: the bromo- and iodo-derivatives are rather more reactive than the chloro-compounds, but the differences are not always considerable. It is suggested that the explosive properties of such mixtures may be explained by the formation of small amounts of highly explosive compounds, such as halogen acetylenes, which cause the explosive decomposition of the entire system. In Table II the minimum impulse (metres × kg.) required to cause explosion is given in Arabic figures, the number of explosions in five tests is shown by the figures in brackets and the strength of the detonation is denoted by I, very feeble, II feeble and III moderate.[111,112]

TABLE II.- EXPLOSIVE PROPERTIES OF MIXTURES OF LITHIUM WITH ORGANIC HALOGEN COMPOUNDS

A recent explosive reaction between lithium and carbon tetrachloride has been described. In order to sample lithium metal from a billet for nitrogen analysis, without exposing the metal to the nitriding action of the atmosphere, attempts were made to cut the billet under carbon tetrachloride. Thin slices of lithium ($^1/_8$–$^1/_{16}$ in.) had already been held under carbon tetrachloride with metal fingers and shaken for some time without incident. A 2·5 in. thick lithium billet was then cut under carbon tetrachloride and as the shear blade touched the metal to make the fifth cut a violent explosion occurred accompanied by a bright yellow flame. Only the faintest mark of the blade was visible on the billet on later inspection. At the time of the explosion the metal had not been exposed to the air in any way and the carbon tetrachloride was very dry; the reaction continued with much crackling and flaming until the carbon tetrachloride was drained from the tank. The main products of the reaction as far as could be identified were carbon and lithium chloride; no smell of phosgene was observed. Large cavities were eaten into the metal. The only peculiar observation made during the first four cuts was that during cutting a few bubbles were evolved from around the cutting edge, and were attributed to local heating from shearing of the metal. The operators of the

Refs. p. 85

shears and two men standing five feet away received burns to the face and other parts.[113]

In the molten state, lithium attacks carbides, silicates, rubber and plastics.[100] The bottom of a porcelain tube, 2 mm. thick, was completely destroyed in 7·5 min. when lithium was heated in the tube at 465° C.[114] The attack on vitreous silica at 250° C. is very rapid and the product of the reaction is believed to be lithium metasilicate, Li_2SiO_3.[115] A special glass has been used in the preparation of lithium metal and has proved to be sufficiently resistant to attack to permit lithium to be cast, provided the metal is solidified rapidly in say ten to twenty seconds after running it into the moulds. This glass contains 2·3% SiO_2, 26·8% B_2O_3, 29·6% Al_2O_3, 35% BaO, 4·4% Na_2O and 1·9% K_2O.[116] Lithium weakens the bonding between oxygen and cobalt, thus reducing the intensity of the blue colour of silicate glass.[117] The appearance, chemical constitution, hardness and electrical conductivity of non-metallic articles containing silica, such as glasses and ceramics, can be altered without change of form or size by heating to 700–900° C. in contact with reducing metals such as lithium, for a sufficient time to transform *in situ* a substantial portion of the siliceous part of the articles into a new material having a metallic appearance. Particles of the metal oxide are embedded in a matrix of an alloy of the metal with silicon.[118]

It is postulated that alkali metals can assume a covalency of four in glasses by accepting co-ordinate links from lone pairs of electrons from oxygen in the silicate network. Experimental work on amber coloured glass shows that when constant amounts of colouring agents are present (iron oxide, sulphur and carbon), the depth of colour is increased when silica is replaced by soda and a similar effect obtained when sodium oxide is replaced with lithium oxide. Replacement of sodium oxide with potassium oxide produces a decrease in depth of colour and further addition of this oxide, at the expense of silica, causes the colour to become paler still until the potassium oxide content is 20%. Further replacement then causes a deepening of colour, a phenomenon which requires further investigation. It is assumed that a deepening of colour is produced by a process analagous to reduction and that with the exception of the special effect of zinc oxide, a decrease in depth of colour is due to an oxidation effect. The alkali metals arranged in order of increasing reducing power (*i.e.* increased basicity) are potassium, sodium, lithium. The colour of selenium-pink glasses changes from brownish pink to bluish pink by replacing sodium oxide with potassium oxide, *i.e.* there is an increase in the oxidizing nature of the batch.[119]

Alkali-metal dispersions which are stable against settling and agglomeration in which the dispersed metal does not exceed 50 μ in size, are obtained by preparing an emulsion of finely divided molten particles of an alkali metal in an inert liquid hydrocarbon having a boiling point above the melting point of the metal in the presence of an emulsifying agent. Lithium, sodium, potassium, rubidium and caesium and alloys of these metals may be used. Emulsifying agents are complex addition products formed between two distinct types of component compounds and are (1) of the general formula, MOR, where M is an alkali metal and R an aliphatic, *cyclo*aliphatic, or aromatic radical and (2) alkali metal organic compounds in which an alkali metal is directly attached to an allylic residue, *i.e.* compounds having at least one residue of the structure C:CCM, where M represents an alkali metal. An example for preparing sodium dispersions is given in Sect. XXV. The unusually finely divided form of the metal makes the dispersions useful as additives for Diesel fuels of inferior ignition characteristics, the effect being to increase the cetane number of the fuel.[120]

REACTIONS OF LITHIUM IN LIQUID AMMONIA

Before describing the specific reactions observed in lithium solutions in liquid ammonia, a brief account of the general behaviour of the alkali metals in this solvent will give some idea of the types of reactions that may occur. There is reasonable evidence to support the view that in liquid ammonia the alkali metals are ionized according to the equation: $M \rightleftharpoons M^+ + e^-$, and that in dilute solutions the electrons are associated with ammonia molecules: $e^- + n\ NH_3 \rightarrow e^-(NH_3)_n$. Since reduction involves the addition of electrons to a given atomic system, it is apparent that such metal solutions are eminently suitable as reducing agents. An atom of sulphur is reduced to a negative ion: $S + 2e^- \rightarrow S^{--}$; $2M^+ + S^{--} \rightarrow M_2S$. A positive ion is reduced to a neutral atom: $Ag^+ + Br^- + M^+ + e^- \rightarrow Ag$ (solid) $+ M^+ + Br^-$. In a reaction of this type the metal formed may be reduced to a lower state of oxidation, it may catalyze the reaction between the alkali metal and ammonia yielding the amide and hydrogen, it may react with the amide so formed, or it may take part in no further reaction. The course of reactions of the following type: $K^+ + e^- + Na^+ + Cl^- \rightarrow KCl$ (solid) $+ Na^+ + e^-$, is determined by solubility relationships. Negative ions may be further reduced: $2M^+ + S_n^{--} + 2M^+ + 2e^- \rightarrow M_2S$ (solid) $+ 2M^+ + S_{(n-1)}^{--}$; $2M^+ + NO_2^- + e^- \rightarrow M_2NO_2$ (solid).

Liquid ammonia has many advantages as a medium in which to carry out reducing reactions: it is a solvent for numerous inorganic and organic substances and such solutions, containing free electrons when the alkali metals are present, provide an infinite surface for reaction; it is only on rare occasions that an excess of the reducing agent is necessary, and many reactions can be followed visually because the initial intense blue colour of the metal solution is discharged as the reaction proceeds. In the absence of metal catalysts and at ordinary temperatures the rate of interaction of the alkali metals with liquid ammonia is negligible compared with the rates of the reactions now under consideration. Where by reason of solubility relationships liquid ammonia is unsuited to a given reaction, the simple amines methylamine and ethylamine may be used. Well documented reviews are available on the reactions of inorganic and organic substances in liquid ammonia and amine solutions of the alkali metals.[1-3]

In the presence of metal catalysts and at elevated temperatures the alkali metals react with liquid ammonia forming the metal amide and liberating hydrogen. The effect on the usual materials of plant construction has been investigated for solutions of sodium in liquid ammonia.[4]

The reactions of lithium in liquid ammonia with the elements oxygen, sulphur, selenium, tellurium, arsenic, antimony and phosphorus have already been described (see pages 70-77). The electrolysis of lithium iodide in liquid ammonia with a platinum anode and a lead cathode results in the formation of a green solution containing lithium polyplumbide to which the formula Li_4Pb_n has been given.[5] When ammonium salts are added to lithium solutions in liquid ammonia, hydrogen and ammonia are produced and the corresponding lithium salt is obtained: $Li^+ + e^- + NH_4^+ + Cl^- \rightarrow Li^+ + Cl^- + NH_3 + H$;[6] $Li^+ + e^- + NH_4^+ + I^- \rightarrow Li^+ + I^- + NH_3 + H$.[7] Liquid hydrogen sulphide reacts with lithium in liquid ammonia solution, in the absence of air, liberating hydrogen and ammonia and forming lithium sulphide.[8] Lithium reacts vigorously with ammonium azide to give lithium azide: $Li + NH_4N_3 \rightarrow LiN_3 + NH_3 + H$.[9] The blue colour of lithium in liquid ammonia is immediately discharged when the solution reacts with a suspension of aluminium iodide hexammoniate, $[Al(NH_3)_6]I_3$, at −70°C. and the solid phase passes into solution. The initial reaction is rapid and is followed by a slow reaction differing little in speed from that of lithium on the solvent. The suggested course of the initial rapid reaction is $[Al(NH_3)_6]^{+++} + NH_3 \rightarrow [Al(NH_3)_5NH_2]^{++} + NH_4^+$; the ammonium ions are destroyed by the metal solution, $NH_4^+ + e^- \rightarrow NH_3 + H$, and the rapid reaction continues until all the aluminium is present as a soluble, relatively stable complex having the empirical formula $Al(NH_2)_{1\cdot5}I_{1\cdot5}$. The net result is the evolution of hydrogen and the accumulation of amide in solution, and the solid products isolated are found to be a mixture of ammonobasic aluminium compounds.[10] Lithium in liquid ammonia solution reacts with the diammoniate of diborane ($B_2H_6,2NH_3$) in the same solvent; on removal of the solvent a mixture of lithium borohydride, $LiBH_4$, and aminoborine, BH_2NH_2 (polymeric) is obtained. Stoicheiometrically the overall process is represented by the following equations: (1) Li (soln.) + $B_2H_6,2NH_3$ (soln.) = LiB_2H_8N (soln.) + $0\cdot5H_2 + NH_3$; (2) LiB_2H_8N (soln.) = $LiBH_4$ (solid) + BH_2NH_2 (polymeric). The formula, LiB_2H_8N accords with the stoicheiometry but does not imply a structure or a particular species. The borohydride and aminoborine are probably present in the solution before removal of solvent because at −78°C. lithium borohydride tetrammoniate appears as the solid phase immediately upon removal of the solvent. If this is the case, the reaction of lithium with the diammoniate of diborane should be expressed as: Li (soln.) + $B_2H_6,2NH_3$ (soln.) = Li^+ (soln.) + BH_4^- (soln.) + BH_2NH_2 (soln.) + NH_3 + $0\cdot5H_2$, and the removal of solvent as: Li^+ (soln.) + BH_4^- (soln.) + BH_2NH_2 (soln.) = $LiBH_4$ (solvate) + BH_2NH_2 (polymeric). The borohydride is separated by excess metal and polymeric aminoborine by the use of ether as solvent. Ammonolysis of the aminoborine occurs with the production of hydrogen unless the solvent is removed at the lowest possible temperature: $BH_2NH_2 + xNH_3 = xH_2 + BH_{2-x}(NH_2)_{1+x}$.[11] The reaction between boron trifluoride and lithium in ethylamine solution proceeds almost quantitatively, three atoms of hydrogen being evolved for each molecule of the trifluoride: $BF_3 + 3C_2H_5NH_2 + 3Li \rightarrow B(C_2H_5NH)_3 + 3LiF + 3H$.[12] Liquid ammonia solutions of the complex, BF_3,NH_3, have been titrated with liquid ammonia solutions of the alkali metals in an apparatus which permits the quantitative recovery of all products. Treatment of solutions of the complex with excess alkali-metal solution, followed by back titration with ammonium iodide, has also been carried out. The titrant and moles of titrant per mole of BF_3,NH_3 by forward titration are Li, 2·91; Na, 2·50; K, 1·00; Cs (back titration), 1·03; KNH_2, 2·6. A straightforward difference in stoicheiometry of the reactions with different alkali metals is shown and equations given are in agreement with experimental results. For lithium the reaction is expressed by: $6Li + 2BF_3,NH_3 + 2NH_3 \rightarrow 6LiF + (NH_2)_2BNHBNH + 3H_2$.[13] Lithium carbonyl, LiCO, is obtained as a white powdery substance when pure dry carbon monoxide is passed through a solution of lithium in liquid ammonia; both air and moisture must be rigidly excluded because of the highly reactive nature of the product which detonates violently with water with instant ignition of the gaseous products, leaving a residue of carbonate and carbon.[14]

Reactions of lithium in ammonia with arsine, phosphine and sodium nitrite have already been described (see page 77).

Dipotassium ammonolithiate, $LiNK_2,2NH_3$ or $LiNH_2,2KNH_2$ or $[Li(NH_2)_3]K_2$, is formed as a greyish but well crystallized solid when lithium and potassium, in the presence of a minute portion of platinum black, are allowed to react with liquid ammonia. The ammonolithiate decomposes in the presence of ammonium salts of the oxygen and halogen acids to give the corresponding salts of lithium, potassium and ammonium. Monorubidium ammonolithiate, $LiNHRbNH_3$ or $LiNH_2RbNH_2$ or $Li(NH_2)_2Rb$, is formed in a similar manner. Rubidium with a minute portion of platinum black is allowed to stand with liquid ammonia until the blue colour of the metal solution disappears and a liquid ammonia solution of lithium is then poured on to it. The ammonolithiate so formed is a greyish crystalline solid. These reactions must be carried out in the absence of air and water.[7] The rates of solution of the alkali metals in liquid ammonia and the rates of the ensuing reactions with nickel bromide, $NiBr_2$, are too rapid for accurate measurement, but both rates increase from lithium to cæsium. The reactions yield nickel and the catalytic activity per unit area of the nickel produced by the reducing metals lithium, sodium, potassium, cæsium is substantially constant.[15]

Numerous organic reactions have been studied in liquid ammonia or ethylamine solutions of lithium and a brief account of some of these is given below.

Saturated hydrocarbons are not attacked by the alkali metal solutions but hydrogen is displaced from acetylene with the formation of the metal salt: $C_2H_2 + Li \rightarrow C_2HLi + H$. Attempts to isolate the acetylide by heating in a high vacuum at 120°C. produce a mixture containing 82% of lithium carbide and 17·6% of the acetylide.[16] The aromatic hydrocarbons, benzene, toluene and xylene, do not react with the alkali metal solutions and may therefore be used as diluents or as solvents for a solid reactant.[1]

Free radicals usually react with the electrons in the alkali metal solutions to form ions: thus triphenylsilicyl gives an intense red solution with lithium in ethylamine from which a crystalline solid, $(C_6H_5)_3SiLi$, may be isolated.[17] Triethylsilicyl does not react with lithium, but the metal catalyzes the reaction: $(C_2H_5)_3SiH + C_2H_5NH_2 + Li \rightarrow (C_2H_5)_3SiNHC_2H_5 + H_2 + Li$.[18] Triethylgermanyl forms lithium triethylgermanide, $LiGe(C_2H_5)_3$, in ethylamine solution and the product is partially aminolyzed in this solvent to give triethylgermane, $(C_2H_5)_3GeH$, and in ammonia is completely ammonolyzed.[19] Monomethyl- and monoethyl-germanes react in almost equivalent amounts with lithium in ethylamine solution to give CH_3GeH_2Li and $C_2H_5GeH_2Li$. On warming to room temperature the white solids become yellow and hydrogen is evolved; secondary reactions also occur and ethane is given off. Ethyl*iso*amylgermane also reacts with lithium in ethylamine but in this case the lithium salt has not been isolated.[20] Triphenylgermanyltriethylsilicon with lithium in ethylamine gives an equimolecular mixture of lithium triethylsilicide and lithium triphenylgermanide.[18] Trisubstituted derivatives of boron and gallium also react with lithium in ethylamine. With trimethylboron the reaction is quantitative: $(CH_3)_3BC_2H_5NH_2 + Li \rightarrow (CH_3)_3BC_2H_5NHLi + H$; concentrated solutions of the salt are unstable and two molecules of methane are produced per molecule of salt. Tributylboron reacts similarly and again concentrated solutions of the lithium salt decompose evolving butane.[21] Trimethylgallium reacts according to the following equations: $Li + (CH_3)_3GaC_2H_5NH_2 \rightarrow (CH_3)_3GaC_2H_5NHLi + H$; $2Li + 2(CH_3)_3GaC_2H_5NH_2 \rightarrow [(CH_3)_3Ga]_2^{--} + 2Li^+ + 2C_2H_5NH_2$; $Li_2[Ga(CH_3)_3]_2 + 2C_2H_5NH_2 \rightarrow 2LiC_2H_5NHGa(CH_3)_2 + H_2$: 39·8% of the gallium reacts according to the first equation, 61·2% according to the second. The product of the first reaction is stable in the dry state as well as in ethylamine solution but the product of the second is measurably stable only at −33°C. and breaks down on removal of the solvent.[22]

Organohalides of silicon, germanium and bismuth react with lithium solutions in ethylamine. Triphenyl- and triethyl-silicon bromides give respectively $(C_6H_5)_3SiC_2H_5NH_2 + LiBr$ and $(C_2H_5)_3SiNHC_2H_5 + LiBr + H$.[18] Diphenylgermanium chloride forms lithium chloride and a resinous material approximating to the composition of diphenylgermanium.[23] Triethyl germanium chloride, bromide, fluoride and iodide react as follows: $2(C_2H_5)_3GeX + 2Li \rightarrow 2LiX + [(C_2H_5)_3Ge]_2$; $[(C_2H_5)_3Ge]_2 + 2Li \rightarrow 2LiGe(C_2H_5)_3$. In ethylamine solution, and more so in ammonia solution, the lithium salt ammonolyzes: $LiGe(C_2H_5)_3 + NH_3 \rightarrow (C_2H_5)_3GeH + LiNH_2$.[19] Organobismuth compounds react with lithium in liquid ammonia forming highly reactive deep red coloured compounds of the type R_2BiLi which decompose slowly to salts, R_3Bi, but are sufficiently stable to react promptly with organohalides.[24]

In its behaviour towards alcohols lithium resembles the alkaline earth metals in that its reactions are slow compared with those of the other alkali metals. With methanol the decolorization of a lithium solution in liquid ammonia is followed by the immediate precipitation of lithium methoxide which is insoluble at −50°C. even in an excess of the alcohol: $CH_3OH + LiNH_3 \rightarrow CH_3OLi + NH_3 + H$. Lithium ethoxide, on the other hand, is very soluble in ethyl alcohol; if the ammonia is driven off without decantation a crystalline mass is obtained which loses alcohol slowly in the cold but rapidly at 100°C., leaving a white amorphous mass of the ethoxide. Similar reactions occur with *iso*butyl and *iso*amyl alcohols. Glycol gives the monolithium derivative, $C_2H_5O_2Li$, which may be transformed rapidly and completely into the dilithium salt by heating at 170–200°C. Lithium differs from the other alkali metals in that it gives the dilithium salt of erythritol and mannitol and not the monoderivative, and in this respect it resembles the alkaline earth metals.[25] In the presence of ethyl alcohol, lithium solutions in liquid ammonia reduce phenolic ethers, giving in some cases remarkably good yields of the reduction products, whereas sodium and potassium under similar conditions have failed to react. This is probably due to the higher normal reduction potential of lithium in liquid ammonia (Li, −2·99 V.; Na, −2·59 V.; K, −2·73 V.), to its high solubility and low molecular weight which permit higher concentrations to be used, and to the fact that the reaction between lithium and ethyl alcohol is slower.[26] By means of the lithium–ammonia–alcohol procedure it has been possible to convert 11-ketosteroids into the corresponding 11-α-hydroxycompounds; the diethyleneketal of cortisone has been transformed into the practically pure 11-*α*-hydroxide compound, and 19-nortestosterone and 19-norandrostenedione have been synthesized from estrone.[27-29]

ORGANOLITHIUM COMPOUNDS

The first organolithium compound was made by Schlenk and Holtz[1] in 1917 and since that date so much work has been devoted to the study of organolithium compounds that their usefulness is now comparable with that of Grignard compounds. They are the most reactive of the organometallic compounds.

The lithium alkyls can be prepared by the method of Schlenk and Holtz, namely, by reaction between lithium and a mercury dialkyl: $2Li + HgR_2 \rightarrow 2LiR + Hg$, but are more usually obtained by the direct metallation process of Ziegler and Colonius[2] in which lithium reacts with an alkyl halide: $2Li + RHal \rightarrow RLi + LiHal$. A third alternative is the indirect metallation process of Gilman[3,4] and Wittig[5] in which an easily prepared alkyl-lithium (e.g. *n*-butyl-lithium) is allowed to react with a bromo-compound which does not itself react directly with lithium: $BuLi + C_6H_5(OMe)Br \rightarrow BuBr + C_6H_5(OMe)Li$.

Some organohalides that react only sluggishly with magnesium give good yields of the lithium derivative: p-bromodimethylaniline gives a 95% yield of p-lithium dimethylaniline,[6] and certain alkenyls which do not form Grignard reagents react with lithium to give the metal compound: $(CH_3)_2C = CHBr + 2Li \rightarrow (CH_3)_2C{=}CHLi + LiBr$.[7] On the other hand, some halides which form Grignard reagents with great ease, for example, polyhalogen-aryl compounds such as p-chlorobromobenzene, are substantially unaffected by lithium.[8]

Halogenated naphthalene with the halogen in the alpha position gives lithium naphthyl, $C_{10}H_7Li$, which may be converted into homologues of naphthalene; when the halogen is in the beta position, binaphthyl is obtained.[9]

Perfluoroalkyl iodides react with lithium in the presence of a solvent to form lithium perfluoroalkyl compounds.[10]

Although many lithium alkyls have been used in synthetic experiments, few have been isolated. Lithium methyl is an anomalous compound, being a white amorphous powder decomposing and burning explosively in air and decomposing without melting on heating; it is insoluble in many organic solvents. On the other hand, lithium ethyl is a colourless crystalline solid which melts to a clear liquid at 95°; it can be purified by sublimation[11] and is soluble in benzene and many other solvents. Higher lithium alkyls constituting a fairly representative series have been prepared, but only occasionally isolated.[12-27]

Most lithium alkyls are now prepared in light petroleum[29] or benzene solution;[28] in ethyl ether they must be used shortly after preparation as they react with this solvent to give saturated and unsaturated hydrocarbons and a

Refs.p.93

lithium alkoxide: e.g. $(Et)_2O + LiEt \rightarrow LiOEt + C_2H_6 + C_2H_4$. Lithium alkyls (except the methyl compound) have low dipole moments[30] and give non-conducting solutions in benzene,[31] from which a covalent structure is deduced and a resemblance between the C–Li and C–F bonds is established qualitatively.

Among the important reactions of lithium alkyls is the formation of fully alkylated metal compounds directly from the anhydrous metal chloride. Thus, gold trichloride and lithium ethyl yield triethyl gold:[32] $AuCl_3 + 3C_2H_5Li \rightarrow Au(C_2H_5)_3 + 3LiCl$. Similar reactions have been observed with germanium[33] and thallium,[34] whilst the use of lithium aryls has enabled the whole series of pentaphenyl derivatives of the P, As, Sb, Bi family to be obtained[35,36] e.g. Ph_5P which has m.p. 124° or Ph_5Bi, m.p. 100–104°. Gilman and his co-workers[37] were able to synthesize the theoretically very important compound $(C_6H_5)_3C.Si(C_6H_5)_3$ analogous to hexaphenylethane, by the reaction of triphenylmethane with a lithium alkyl to give lithium triphenylmethyl: $(C_6H_5)_3CH + LiR \quad RH + (C_6H_5)_3CHLi$. The latter compound reacts with triphenyl silicon chloride to give the required substance: $(C_6H_5)_3CHLi + (C_6H_5)_3SiCl \rightarrow (C_6H_5)_3C.Si(C_6H_5)_3 + LiCl$. This analogue of hexaphenylethane is colourless and highly stable, m.p. 340–345°, showing no tendency to ionize across the C–Si bond.

The ability of lithium alkyls to react with double bonds is almost unique and makes them very valuable synthetic agents.[38] The reaction between ethylene and lithium butyl gives a series of lithium alkyls: these react with formaldehyde to give the primary alcohol series C_7–C_{13}, approximately in the proportions 5:5:3:1. In this way, by using different lithium alkyls, the whole homologous series of paraffin alcohols can be obtained.[39]

$$\begin{aligned} C_2H_4 + BuLi &\rightarrow C_6H_{13}Li + CH_2O \rightarrow C_7H_{15}OH \\ C_2H_4 \downarrow\ & C_8H_{17}Li + CH_2O \rightarrow C_9H_{19}OH \\ C_2H_4 \downarrow\ & C_{10}H_{21}Li + CH_2O \rightarrow C_{11}H_{23}OH \\ C_2H_4 \downarrow\ & C_{12}H_{25}Li + CH_2O \rightarrow C_{13}H_{27}OH \end{aligned}$$

Further, lithium alkyls will add to the –N=CH– linkage in pyridine and analogous compounds leading to $-N{=}\underset{|}{C}-R$ compounds, R being the alkyl from the organometallic reactant.

Reaction of lithium alkyls with double bonds, followed by the action of carbon dioxide on the product, is an excellent and expeditious way of synthesizing complex carboxylic acids:[40-42] $(C_6H_5)_2C{=}CH_2 + Li(C_3H_7) \rightarrow (C_6H_5)_2CLi{-}CH_2C_3H_7 + CO_2 \rightarrow (C_6H_5)_2C(COOH)C_4H_9$. With dimethylbutadiene, butadiene, isoprene and piperylene,[44] two atoms of lithium react, leading to the formation of large unsaturated hydrocarbon molecules.

It is not possible here to list all the applications of the lithium organic compounds in organic syntheses, but the following are exceptional as being reactions which can be carried out expeditiously only by the action of lithium derivatives.

(1) The synthesis of azaporphins direct from *o*-phthalodinitrile.[43]

(2) The use of lithium alkenyls, particularly lithium vinyl, $CH_2{=}CHLi$, in organic syntheses such as the formation of phenylpropenylcarbinol, $C_6H_5.CHOH.CH{=}CH{-}CH_3$, from propenyl lithium $CH_3CH{=}CHLi$ and benzaldehyde.[45-48]

(3) Synthesis of *cyclo*hexenyl derivatives from bromo*cyclo*hexenyl compounds without loss of unsaturation.[49,50]

Thus, lithium *cyclo*hexenyl will yield phenyl*cyclo*hexenylcarbinol with benzaldehyde, or decahydrofluorenone with bromo-*cyclo*hexene.

(4) The lithium alkynes, e.g. $CH{\equiv}CLi$ are readily formed; they are much more soluble than the analogous sodium compounds and give better yields[51] of -yne compounds, e.g. $RC{\equiv}CLi + BrBu \rightarrow RC{\equiv}$

$C(CH_2)_3CH_3$, a reaction which has considerably facilitated the total synthesis of vitamin-A.[52]

Lithium aryls are easily obtained by the direct metallation of aryl chlorides or bromides; and in many cases where Grignard compounds are formed from chlorides only with great difficulty, lithium reacts readily. Where, owing to steric factors, lithium will not react directly (e.g. with chloromesitylene), indirect metallation with lithium propyl is usually effective.[53-58] Indirect metallation by displacement of hydrogen from a benzene ring is possible in some instances; e.g. anisole, $C_6H_5.OMe$, yields the *o*-lithium derivative, $C_6H_4(Li)OMe$, with phenyl lithium.[59-61] One of the more unusual reactions of phenyl lithium is with nitrous oxide giving first $C_6H_5N{=}N.OLi$ and then a series of decomposition products.[62]

SECTION V

LITHIUM ALLOYS

By MRS. F. DICKINSON

The term 'alloy' has been defined as 'a mixture with metallic properties, composed of two or more elements of which one at least is a metal'. Alloys differ not only according to the elements of which they are composed but also according to the crystal structure and the distances between the atomic centres in the crystal lattice. Usually, face-centred cubic systems are more ductile but less strong than body-centred cubic alloys; hexagonal and other non-cubic alloys are not generally as malleable as cubic structures. The properties of an alloy are also determined to a large extent by the distribution of phases in the system. The high strength of age-hardened alloys is accounted for by the fine dispersion of a second phase throughout the alloy; where, on annealing, the second phase is distributed as coarse particles, the strength is not nearly so great. Most solid solutions are of the 'substitutional' type in which one kind of atom in the crystal structure is replaced by other metal atoms at random; the 'interstitial' type of solid solution is one in which atoms of small radii are accommodated in the interstices of the lattice of the other metal. Only when the components have the same crystal structure is complete solid solubility possible; the greater is the difference in atomic size, the more limited is the solid solubility, and no example of complete solid solubility is known where the difference in atomic radii of the metals is greater than 15%. A metal of lower valence tends to dissolve one of higher valence to a greater extent than vice-versa, and generally metals having the same valence in the alloy as in their usual compounds exhibit greater solubility than those having different valencies. The greater is the difference in atomic size and valence, the steeper is the solidus curve and the greater the freezing range; also the farther apart are the metals in the electrochemical series, the less likely are they to form solid solutions with each other. When metals combine with each other according to their normal valencies they form 'valence compounds'. 'Electron compounds', on the other hand, are phases with wide ranges of homogeneity and are sometimes referred to as intermediate phases rather than compounds; their crystal structures are determined by the number of valence electrons in the alloying atoms. In the compound Cu_5Sn, for example, the alloying valence of copper is one and that of tin is four; the total number of valence electrons is nine and, since there are six atoms altogether, the electron-atom ratio is 9:6 or 3:2. This ratio is found in compounds which have the beta-brass or beta-manganese structure; for gamma-brass the ratio is 21:13 and for the hexagonal structure of epsilon-brass it is 7:4. Many intermetallic compounds are such that small atoms fit interstitially between the metal atoms in the structure, but these compounds should not be confused with interstitial solid solutions in which the small atoms are distributed at random. The essential difference between a solid solution and a compound is that in the former the atoms of the different metals are distributed at random on the lattice points, but in a compound, atoms of each kind occupy assigned lattice points. When a shift of the atoms from random to assigned positions occurs, the compounds so formed are described as super-lattice compounds and the above type of change is one of order-disorder.

With regard to the physical properties of alloys, the thermal and electrical conductivities of a solid solution are less than those of the pure metal. Matthiessen's rule states that as small amounts of an alloying element are added in solid solution to a metal, the increase in resistance is independent of temperature; for mixtures of insoluble phases, the resistivity follows the law of mixtures. Generally, the lattice parameter and density are increased by a heavier metal in solid solution and decreased by a lighter one. Attraction between unlike atoms causes the lattice to be generally slightly more compressed than the law of mixtures predicts. The added element in interstitial solid solutions always expands the lattice but the effect on density is slight. The law of mixtures generally applies to the specific heat and coefficient of thermal expansion, but not in the case of the iron-nickel system. Some alloying elements stabilize a particular allotropic modification whereas others cause it to disappear. In the absence of compound formation, the heat of mixing is generally small, sometimes positive, sometimes negative, but when stable compounds are formed, the heat of mixing is positive and may be large. Shrinkage from the liquidus to solidus and from solidus to room temperature is important in the control of sound castings; fluidity is also important. In their introduction to the study of alloys Kirk and Othmer[1] also discuss the mechanical properties of alloys, their corrosion resistance, and treatments such as melting, casting, sintering, hot working, cold working, surface treatments and heat treatment.

The following methods for the detection of intermetallic compounds have been discussed: *X*-ray investigation, thermal expansion, the determination of electrical resistance as a function of temperature and the examination of magnetic properties as a function of concentration and temperature.[2]

In the following account of the behaviour of lithium with other metals, percentage composition refers to weight per cent. unless otherwise stated.

Lithium and sodium are practically immiscible; since, however, the melting point of lithium is depressed by the addition of sodium and that of sodium by the addition of lithium, the metals must be soluble in each other to some extent. According to earlier workers[3-5] the melting point of sodium is lowered by about 2°C. by 0·5% of lithium and that of lithium from 179°C. to 162°C. by 7% of sodium. Böhm and Klemm give the lowering of the melting point of sodium (97·5°C.) as 6° to 7°C. and that of lithium (178°C.) as 12°C. No compound of lithium and sodium has been reported.[6] In an investigation of the effect of geometrical factors on the stoicheiometric formula of metallic compounds it is observed that in the system, Na–Li, where the radius ratio is 1·22:1, no compound is formed.[7] A series of spectrograms has been obtained with lithium maintained at 850°C. and sodium at 435°C., 460°C., 485°C. and 510°C. and also with a constant high sodium vapour pressure, with increasing lithium vapour pressure; no evidence of bonds attributable to a sodium-lithium molecule has been found in the region of 3000 A. to 8000 A. and this is the only binary compound of the alkali metals which has not been found.[8] The phase diagram of the sodium-lithium system has been more recently investigated to evaluate the solubility of molten lithium in sodium. The metals were melted in a mild steel crucible of 10-10 low-carbon steel, which was tapered at its lower end and was open to another crucible through a small orifice. The two crucibles were fitted into an apparatus which could be filled with argon and evacuated, and means were provided to determine the temperature of the melts in the lower crucible; the molten metals in the upper crucible were freed from oxide by evacuating the system under argon when an intact 'skin' of oxide remained in the upper crucible and the molten metals passed through to the lower one. The liquidus and solidus of a 50 vol.-% alloy, *i.e.* 37 wt.-% of lithium, were determined by thermal analysis as also was the melting point of lithium. The composition of the two liquid layers in the immiscibility region was determined by chemical analysis, and the limits of the immiscibility region were calculated from the available experimental data by applying Van Laar's equations for activity coefficients in a two component solution. It was found that the freezing point of lithium was reduced from 179·4°C. to 171°C. by the addition of 3·3 atomic-% of sodium and that at 171°C. sodium and lithium formed two immiscible liquid phases of composition 3·3 and 86·9 atomic-% of sodium in equilibrium with solid lithium. The eutectic composition of the sodium-rich alloy was at 96·3 atomic-% of sodium and the eutectic temperature was 93·4°C. The calculated compositions of the two liquid layers of the complete immiscibility loop are given in Table I.

TABLE I. - COMPOSITION OF LITHIUM-SODIUM ALLOYS

Equilibrium Temperature °C.	Composition of Phases, Mole Fraction			
	Top Layer		Bottom Layer	
	Li	Na	Li	Na
171	0·967	0·033	0·131	0·869
200	0·951	0·049	0·173	0·827
250	0·910	0·090	0·270	0·730
300	0·824	0·176	0·424	0·576
320	0·743	0·257	0·529	0·471
327·3	0·66	0·34	0·66	0·34

Diagrams of the apparatus and of the phase system are given.[9] Subsequently the same authors have said that 3·8 atomic-% of sodium reduces the freezing point of lithium from 179·4 to 171°C. Howland and Epstein have studied the sodium–lithium phase system by thermal analysis in the liquid and solid regions to temperatures in excess of 400°C. They find that two liquid phases separate at 170·6°C. with compositions of 3·4 and 91·6 atom-% of sodium. The critical solution is 442° ± 10°C. at a composition of 40·3 atom-% of sodium. (Salmon and Ahmann[9] by extrapolating their low temperature data obtain a critical solution temperature of 379°C. at a composition of 35 atom-% of sodium). The freezing point of pure lithium is found by Howland and Epstein to be depressed from 180·5°C. to 170·6°C. by the addition of 3·4 atom-% of sodium and the freezing point of pure sodium from 97·8° to 92·2°C. by the addition of 3·8 atom-% of lithium. One liquid phase exists in equilibrium with pure lithium from 170·6°C. to 92·2°C. Correlation of the experimental data with the Scatchard–Hildebrand regular solution model using the Flory–Huggins entropy correction is discussed and the suggestion is made that instead of the liquid phase containing only the species lithium and sodium, there may be some chemical combination. Preliminary experiments by *X*-ray examination and other techniques have given no indication of anything but pure sodium and lithium as the solid separated phases, although admittedly the presence of a solid solution region of no more than a few tenths of an atom-% would probably have escaped detection.[10]

Masing and Tammann,[4] in their investigation of the lithium–potassium system, found that the melting point of one of the alkali metals was lowered by the addition of the other, but Böhm and Klemm[6] showed that the melting point of the two alkali metals in the systems lithium–potassium, lithium–rubidium and lithium–caesium remained unaltered by the addition of one of the metals to the other, the metals in the above system being almost completely

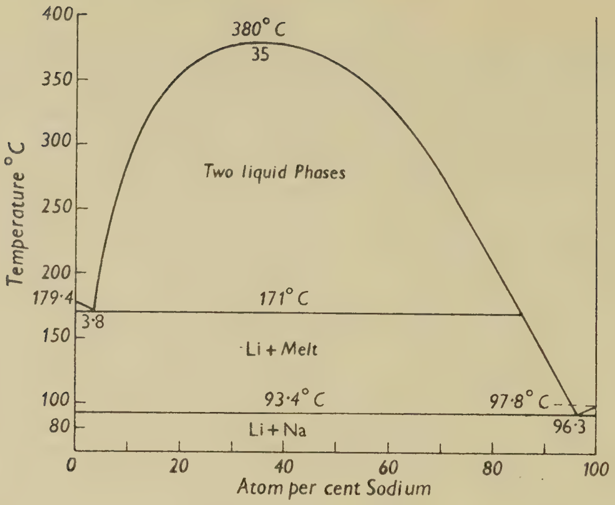

FIG. 1. EQUILIBRIUM DIAGRAM OF THE LITHIUM–SODIUM SYSTEM.[9]

immiscible. The vapours of two dissimilar alkali metals form diatomic molecules such as LiK, LiRb and LiCs.[11] Values for the heat content and entropy at temperatures from 400° to 2000°K. for LiK (gas), LiRb (gas) and LiCs (gas) have been tabulated and the following equations given for the heat content:-

$$\text{LiK (gas):}\quad H_T - H^{\text{gas}}_{298\cdot16} = 8\cdot94T + 0\cdot14 \times 10^5T^{-1} - 2713$$

$$\text{LiRb (gas):}\quad H_T - H^{\text{gas}}_{298\cdot16} = 8\cdot94T + 0\cdot11 \times 10^5T^{-1} - 2702$$

$$\text{LiCs (gas):}\quad H_T - H^{\text{gas}}_{298\cdot16} = 8\cdot94T + 0\cdot09 \times 10^5T^{-1} - 2696$$

The values obtained from the above equations are accurate to 1% between 298^c and 2000°K.[12] The possible effect on solid solubility relations of the mutual distortion of the electron clouds of the component ions in a binary alloy may be of importance for alloys containing small ions bearing a high charge. For dilute solutions an estimate can be made of the extra energy, Δ_{12}, associated with the solution of metal 2 in metal 1 to form an alloy.[13] In the case of solid-solution formation the variation of Δ_{12} with composition must be considered. By assuming that Δ_{12} varies linearly with composition, Henry and Raynor[14] have shown that if Δ_{12} is large, limited solid solution is to be expected, while if Δ_{12} is small, extensive or complete solid solution formation is possible. Calculations for the alkali metals taken in pairs give results in good agreement with experimental work and solid solution formation is restricted in all the possible systems to potassium–rubidium, potassium–caesium and rubidium–caesium, for which extensive solid solutions exist.

Lithium-copper alloys containing 1·7 to 94·01 atomic-% of lithium were prepared by Pastorello[15] by fusing the metals in nickel-chromium steel crucibles in an atmosphere of argon. Alloys containing 1·7, 9·9 and 14·38 atomic-% of lithium resembled pure copper in colour; those with higher percentages of lithium were of a colour approaching the metallic gray of lithium. All the alloys were ductile and those with a high lithium content were almost as soft as lithium itself; they were all attacked by water. An *X*-ray examination of an alloy containing 50 atomic-% of lithium showed

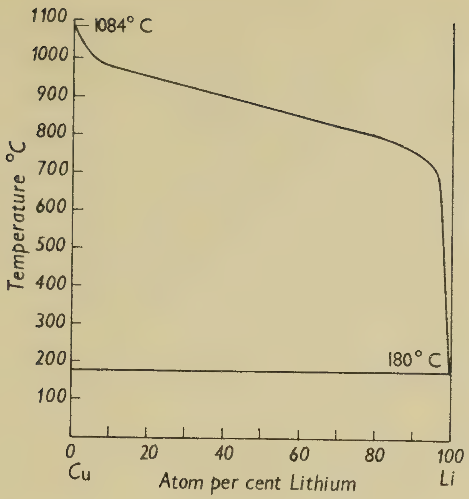

FIG. 2. EQUILIBRIUM DIAGRAM OF THE LITHIUM-COPPER SYSTEM.[15]

diffraction lines which corresponded with the normal structures of copper and lithium; no intramolecular compound and no solid solutions were formed. The depression of the melting point of copper was found to be almost linear for alloys containing 10 to 90 atomic-% of lithium, the eutectic temperature being apparently only slightly lower than the melting point of lithium. Other authors have referred to Pastorello's work.[5,15-17] Oxygen and other inclusions and gases are removed from molten copper by treatment with approximately 0·025% of a lithium alloy, such as a 50-50% lithium calcium alloy; a molten slag of low specific gravity is produced on the surface of the melt and is not entrapped in the casting, and no new impurities are introduced. The treated copper free from oxygen and inclusions is described as lithium copper. Its crystallization temperature is raised; it can be annealed at considerably higher temperatures without its conductivity being lowered, and the resultant bright anneal is attractive in appearance. The lithium-calcium content, usually less than 0·01%, tends to protect the copper against oxidation. Lithium copper has a high density and strength and the successful development of high conductivity lithium copper has led to the industrial development of lithium alloy treatment; thus an increased electrical conductivity, averaging more than 2% greater than has been obtainable with any other deoxidizing agent, has resulted when high conductivity, high strength bronzes have been subjected to the above treatment.[18] The electrical conductivity of copper is improved by treatment with 0·002–0·03% of lithium.[19] Lithium acts as a degasifying agent in welding material consisting of 78–90% of copper, 5–9% of tin and 3–9% of zinc.[20] The effect of lithium additions to high conductivity copper, gun-metal, nickel bronze and copper-aluminium alloys has been examined.[21,22]

Lithium-silver alloys were prepared by Pastorello by heating the metals in nickel-chromium steel crucibles in an argon atmosphere. At about 500°C. fused lithium reacted violently with silver, especially when the latter was finely divided, and heat was evolved indicating the formation of intermetallic compounds. For alloys rich in lithium, it was necessary to heat to about 700°C.; for the preparation of those less rich in lithium, a temperature near the melting point of silver was required. Alloys containing 85·5 to 93·5 atomic-% of lithium were malleable; those containing 65·8 to 93·5 atomic-% of lithium gave in liquid ammonia the characteristic blue colour of lithium solutions; alloys with 48 to 52 atomic-% of lithium gave no appreciable blue colour in liquid ammonia, indicating the existence of the compound, LiAg. This compound was found to have a cubic lattice of the cæsium chloride type with *a* 3·225 A. and density 5·68. The presence of a second compound, Li_3Ag, was also observed. The compound, LiAg, and silver were present in alloys containing less than 48 atomic-% of lithium; two compounds, LiAg, and Li_3Ag were considered to be present in alloys with 56 to 72 atomic-% of lithium and those with 80 to 100 atomic-% of lithium were eutectic mixtures of lithium with the compound, Li_3Ag. The system was studied by *X*-ray analysis.[23] By means of thermal analysis, the same author found the melting point of the compound, LiAg, to be 955°C. and that of the compound, Li_3Ag 450°C.; three eutectic points were found at 610°C., 410°C. and 180°C., corresponding respectively to the concentrations, 30, 70 and 100 atomic-% of lithium. The introduction of 0·35 weight-% of lithium depressed the melting point of silver by about 20°C. and no solid solutions were found to exist.

An *X*-ray study of the crystalline structure of the compound, LiAl, showed that not only had this substance the same structure as the compound, LiAg, but it also had a similar lattice constant, *a* 3·23 A., which agreed with the fact that silver and aluminium have substantially the same atomic diameter, 2·88 and 2·87 A. respectively.[24 25] Silvery white and finely crystalline lithium-silver alloys, containing about 50 atomic-% of lithium, were prepared by Zintl and Brauer, who confirmed the existence of the phase, LiAg, which was shown to have a beta-brass structure, but their results for the lattice constant, 3·168 ± 0·003 A., and density, 6·25, were different from those of Pastorello. The number of atoms per unit cell was 2·1; for beta-brass the number is 2. The density was considered by these workers to be too high, owing probably to the instability of the compound at ordinary temperatures, but there was no doubt that the unit cell contained two atoms.[25] According to Perlitz, the compound, Li_3Ag, has a simple cubic structure with *a* 9·94 A.; the unit cell contained 52 atoms and the densities for alloys containing 76·3 and 80·2 atomic-% of lithium were 3·70 and 2·35 respectively, the volume per atom for each being[5,13,21] 18·8 A^3. More recently, the lithium-silver system has been reinvestigated because the results obtained for the ternary magnesium-silver-lithium system could not be reconciled with the previously accepted equilibrium diagram for lithium-silver. The new equilibrium diagram is considerably different from that of Pastorello; the liquidus curve falls relatively smoothly from the freezing point of silver to a eutectic with 89·2 atomic-% of lithium at 145·5°C. and then rises to the freezing point of lithium. The solubility of lithium in silver, alpha phase, is 46·6 atomic-% of lithium at room temperature and 60·8 atomic-% at 317°C. The solid solubility of silver in lithium is approximately one atomic-% at room temperature and 9 at 145·5°C. The beta phase, LiAg, is formed in the composition range 50–60·8 atomic-% of lithium from the alpha phase by a reaction in the solid state; in the range 60·8 to 77·0 atomic-% of lithium it enters into equilibrium with the liquid: $\alpha \rightleftharpoons \beta$ + liquid (317°C.). The γ_3 phase is formed by a reaction in the solid state from the beta phase or by the reaction $\beta \rightleftharpoons \gamma_3$ + liquid (164°C.); at 154°C. the γ_3 phase and the liquid react to give the γ_2 phase. The γ_1 phase is formed in the solid state at higher lithium contents. The β, γ_3, γ_2 and γ_1 phases include the compositions LiAg, Li_9Ag_4, $Li_{10}Ag_3$ and $Li_{12}Ag$ respectively. The diffraction pattern of the beta phase is characteristic of the cæsium chloride structure, and at the composition LiAg the centres of the silver atoms are 3·163 kx apart. The γ_3, γ_2 and γ_1 phases appear to be closely related structurally and to possess gamma-brass structures. The intermediate phase examined by Perlitz[21]

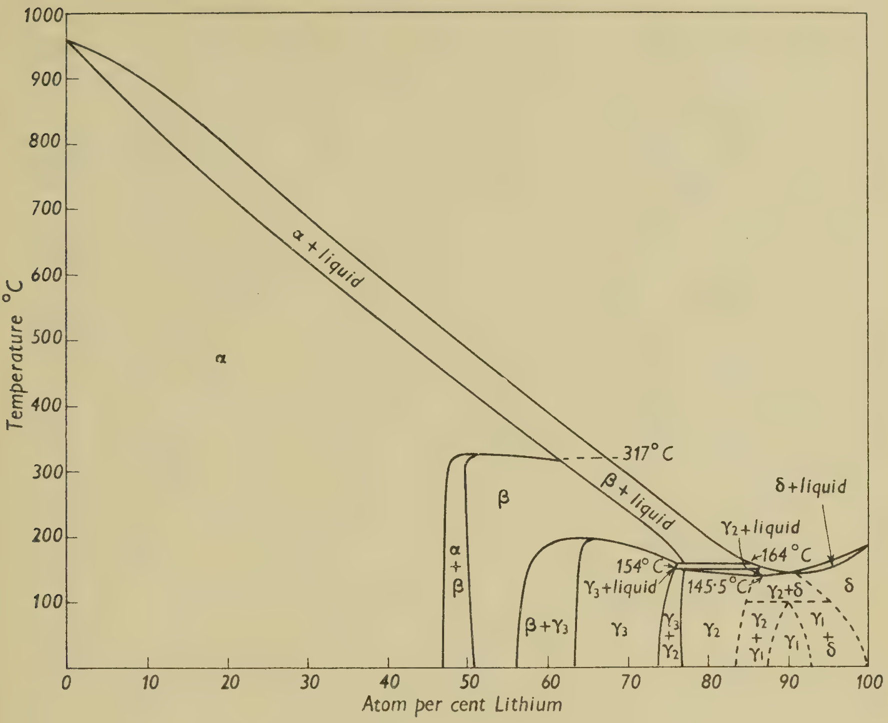

FIG. 3. EQUILIBRIUM DIAGRAM OF THE LITHIUM-SILVER SYSTEM.[27]

corresponds with the γ_2 phase, the side of the unit cell being 9·68 kx at 79·56 atomic-% of lithium. All the observed diffraction lines could also be accounted for on the basis of a face-centred cubic unit cell of side 6·50 kx. The newly discovered γ_3 phase has a large cubic unit cell of side 9·49 kx at the silver-rich composition limit. All the lines for the γ_1 phase at 91·65 atomic-% of lithium indicate a large cubic unit cell of side 9·80 kx.[27] Hume-Rothery, Betterton and Reynolds have investigated the factors controlling the composition limits of phases with the gamma-brass structure in different alloy systems and although the wide range of data agrees with accepted theory, the phase $Li_{10}Ag_3$ is an exception.[28]

In a study of the lithium-gold system, an alloy containing 44 atomic-% of lithium showed exclusively on X-ray examination the lines of a cubic lattice of dimensions approaching those of the gold lattice; another alloy with 52 atomic-% of lithium gave a new interference pattern which could not be explained. In view of the instability of the compound LiAg at room temperature, attempts were made to obtain the beta-brass structure for a similar lithium-gold compound by quenching, but without success.[5,25]

Alloys of lithium and magnesium were prepared by Masing and Tammann;[4,5] those containing 81 and 95% of magnesium were shown by microscopical examination to be homogeneous while two crystalline types were observed in an alloy containing 89% of magnesium; the liquidus curve rose from the melting point of lithium, 179°C., to that of magnesium, 650°C. By means of thermal analysis, measurement of specific conductivities of solid alloys and *X*-ray examinations, Grube, Zeppelin and Bumm[29] obtained the complete phase diagram for this system; the melting point of magnesium was 650°C. and the magnesium-rich alpha-phase was found to extend up to a concentration of 16·3 atomic-% of lithium, with a eutectic point at 587·5° and 21·8 atomic-% of lithium. By plotting lattice constants of alloys containing 20 to 40 atomic-% of lithium against atomic-% of lithium, the limits of a homogeneous region were found to extend from 21·8 to 30·8 atomic-% of lithium, and a maximum melting point, estimated as 592°C. at 28·6 atomic-% of lithium, was assumed to be the melting point of a compound Li_2Mg_5. From the maximum melting point the liquidus curve fell continuously to the freezing point of lithium at 179°C.[5,17,29] Saldau and Shamraiǐ found that magnesium forms three solid phases with lithium; the limits of the alpha-phase ranged from 10 atomic-% of lithium at 15°C. to 12·5 at 465°C. and 19 at 500°C., cutting the eutectic line at 588·2°C. and 21 atomic-% of lithium. According to microscopical examination the compound Li_2Mg_5 does not exist. A definite compound, $LiMg_2$, which melts without decomposition at 600°C., forms solid solutions (beta phase) with both its components in the region 29 to 95 atomic-% of lithium. A solid solution of magnesium in lithium, the gamma-phase, was observed between 98 and 100 atomic-% of lithium.[30,31] By microscopical examination of solid alloys and by thermal analysis Henry and Cordiano constructed an equilibrium diagram for the lithium–magnesium system. The limits of solid solubility were obtained from a series of heat-treating and quenching experiments. Their results showed that the alpha-phase was formed up to 4·9 weight-% of lithium; the beta-phase then began to appear as a broken net-work around the alpha crystals and at 10·9 to 15% of lithium only the beta-phase was visible. At room temperature the limits of the solid solubility of the alpha- and beta-phases were 4·9 and 10·6% of lithium respectively. For the alpha-phase, the solid solubility rose almost vertically from room temperature to 580°C.; for the beta-phase the solubility at 591°C. was 9·9% of lithium. Lithium and magnesium were soluble in the liquid state and partially soluble in the solid state, the curves of primary solidification intersecting at a transition point at 591°C. and 13% of lithium. A peritectic reaction between the alpha-solid solution and melt to form a lithium-rich solid solution was indicated, rather than a eutectic type.[5,16,32] By *X*-ray examination of alloys containing 6·6 to 7·3% of lithium the solubility of lithium in magnesium has been shown to be 5·7% irrespective of the temperature. The density of the alloys decreased but the Brinell hardness remained almost constant when the lithium content was increased[33] (see Table II).

TABLE II. - DENSITY AND HARDNESS OF LITHIUM–MAGNESIUM ALLOYS

Lithium wt.%	0	1·09	2·01	2·43	3·43	4·21	4·85
Density	1·741	1·700	1·670	1·657	1·628	1·607	1·589
Brinell Hardness $^5/_{62}$, $^5/_{30}$	32·0	33·2	31·5	35·0	35·0	32·3	31·9

Hume-Rothery and co-workers found that the alpha-solidus for the lithium–magnesium system was in good agreement with that of Grube, Zeppelin and Bumm[29] but distinctly lower than that given by Saldau and Shamraiǐ;[31] the eutectic temperature was found by thermal arrests to lie between 586° and 592°C., while annealing experiments gave 588·3 to 584·8°C. The solubility of lithium in magnesium was found to be 17·0 atomic-% at the eutectic temperature, between 17·29 and 17·72 at 400°C. and 17·24 at 300°C. The beta-phase was shown to possess a body-centred cubic structure with a random arrangement of atoms at high temperatures and probably an ordered structure of the Fe_3Al type at lower temperatures. The beta-phase alloys were found to be ductile and the possibility of obtaining strong body-centred cubic alloys, lighter than magnesium, in this range of composition has been discussed.[16,34] In a later paper, Shamraiĭ confirms the dystectic formation of the beta-phase, in agreement with Grube, Zeppelin and Bumm and contrary to the peritectic formation asserted by Henry and Cordiano.[32] Alloys with 21·8 and 25·75 atomic-% of lithium are distinctly of the eutectic type and the 28·7 atomic-% alloy is a single phase. On the melting diagram, the two solidus branches intersect the liquidus branch at 600°C. and 33·3 atomic-% of lithium corresponding to the composition $LiMg_2$ and not to Li_2Mg_5 as claimed by Grube, Zeppelin and Bumm. The solid solubility gap between the alpha- and beta-phases extends from 11 to 30 atomic-% of lithium; the eutectic of alpha- and beta-phases lies at about 27 atomic-% of lithium at 588°C. There is a second solubility gap between 95·7 and 97·4 atomic-% of lithium.[35] A phase diagram for compositions ranging from 0 to 33 atomic-% of lithium has been more recently investigated by Catterall. The alpha-phase has the close-packed hexagonal structure of magnesium whilst the beta-phase has the body-centred cubic structure of lithium. The solid solubility limits expressed as atomic-% of lithium are: 28·3% at 350°C.; 27·8% at 450°C.; 26·7% at 550°C.; 25·3% at 575°C. and 24·1% at 588°C.[36] Freeth and Raynor have confirmed that there is a maximum on the beta-liquidus, 29·0 to 29·4 atomic-% of lithium at 594°C., and the invariant reaction involving the magnesium-rich solid solution, the alpha-phase with the beta-phase and the liquid is a eutectic reaction at 588°C. A detailed study of the form of the alpha + beta/beta boundary shows that although the boundary is almost vertical from 100°C., 29·9 atomic-% of lithium, to 500°C., 29·0 atomic-% of lithium, it bends sharply towards lower lithium contents above 500°C. and intersects the eutectic horizontal, liquid $\rightleftharpoons$ alpha + beta at 24·5 atomic-% of lithium.[37] The structure of magnesium–lithium beta-phase alloys has been investigated by Berry and Raynor.[38] A plot of lattice spacing versus lithium content indicates that the (alpha + beta)/beta boundary at 200°C. lies at 30·3 at.-% Li. An alloy containing 34 at.-% Li shows the presence of both the beta phase and a cubic structure of unit-cell 9·7 kx. The systematic absences and the relative line intensities in the diffraction patterns can be accounted for by a structure with 32 atoms per unit cell. The lattice spacing is nearly equal to $2\sqrt{2}a$ where a is the lattice spacing of the body-centered cubic beta structure.

Lithium–magnesium alloys tarnish rapidly at room temperature but remain silvery almost indefinitely when immersed in liquid nitrogen. Solid solutions of magnesium in lithium are partially transformed at low temperatures; a phase identified as face-centred cubic is produced in some of the solid solutions of magnesium in lithium during cold work at low temperatures. This phase has a density almost the same as that of the usual form and a unit cell dimension of 4·40 A.; it forms with audible clicks during cold working at a temperature below a critical temperature *Ms*, and increases in amount with increasing deformation at any temperature below *Ms*. The polycrystalline metal is hardened by transformation on cooling and softened by annealing in the neighbourhood of the reversion temperature, Ac, to the body-centred cubic structure. *X*-Ray diffraction tests give a value of 130° ± 10°K. for the transformation temperature of an alloy containing 12 atomic-% of lithium; the reversion temperature is 15° to 30° higher. The highest magnesium content at which appreciable transformation occurs on cold working is about 25 atomic-%

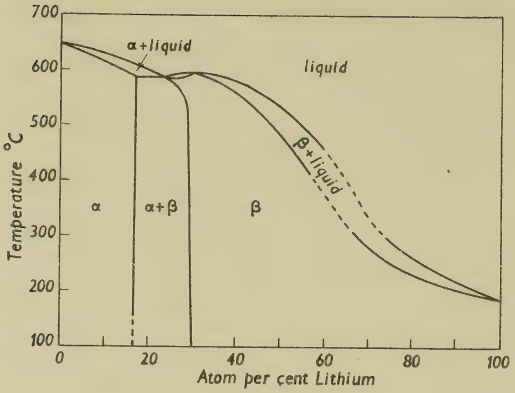

FIG. 4. EQUILIBRIUM DIAGRAM OF THE LITHIUM–MAGNESIUM SYSTEM.[37]

and on simple cooling about 16 atomic-%.[39] The transformation characteristics of a lithium–magnesium alloy containing 12·4 at.-% of magnesium have been further investigated by Barrett and Clifton. In fully annealed fine-grained specimens the critical temperature, *Ms*, which is near 125° K., is slightly lower after annealing near 200° K. than at 300° K. Tests for possible stabilization of the body-centered-cubic phase by annealing in the range of 110°–155° K. during an interrupted cooling experiment discloses no stabilization greater than the estimated error of the best individual experiments. No stabilization of the low temperature phase, hexagonal close-packed structure, is found after annealing at 145°–173° K. during interrupted heating experiments. After cooling below the critical temperature, *Ms*, reversion to the body-centred cubic phase begins slowly as soon as the temperature begins to rise, but rapid reversion begins only when a temperature, *Mr*, is reached which is always higher than *Ms*. The temperature *Mr* and the entire reversion curve above *Mr* shifts to higher temperatures as the previous minimum temperature is decreased. When reversion is interrupted and the specimen again cooled, decomposition of the body-centred cubic phase begins at a temperature, *Ms'*, which is a few degrees above *Ms* and is higher the greater is the % of hexagonal close-packed phase in the specimen.[40]

The density at room temperature, the specific resistance, P_{oo}, at 0°C. and atmospheric pressure, the temperature coefficient of resistance measured between room temperature and 0°C. and expressed as fractional changes of resistance per degree in terms of resistance at 0°C. as unity, of lithium–magnesium alloys are given by Bridgman. (See Table III). The effects of pressure up to 100,000 kg./sq.cm. on the electrical resistance, up to 40,000 kg./sq.cm. on volume compression and up to 80,000 and sometimes 100,000 kg./sq.cm. on the plastic shearing strength, all properties determined at room temperature, are also given. The densities vary almost linearly with composition for alloys containing 100, 99·5, 99·0, 80·0, 60·0, 40·0, 20·0, 10·0, 5·0 and 0 at.-% of lithium. The temperature coefficients drop markedly below the values for the pure metals. Specific resistances plotted against composition show the expected catenary shape for solutions as contrasted with a linear relationship for mixtures. Solubility limits at room temperature are little affected by pressure and there is a general absence of hysteresis or seasoning effects on the initial application of pressure.

Electrical resistance measurements and volume compressions are also given. An alloy, Li(80), Mg(20 at.-%), appears to undergo a polymorphic transition under the action of shearing stress at high pressures.[41]

TABLE III.- DENSITY, SPECIFIC RESISTANCE, AND TEMPERATURE-COEFFICIENT OF RESISTANCE OF LITHIUM-MAGNESIUM ALLOYS

At.-% Li	At.-% Mg	Density	$\rho_{oo} \times 10^6$	Temperature Coefficient $\times 10^2$
100·0	0	0·536	9·17	0·445
99·5	0·5	0·564	11·9	0·438
99·0	1·0	0·536	10·0	0·437
98·0	2·0	0·538	10·1	0·427
80·0	20·0	0·803	24·0	0·136
60·0	40·0	1·070	23·0	0·161
40·0	60·0	1·335	16·0	0·250
20·0	80·0	1·488	11·9	0·252
10·0	90·0	1·644	11·0	0·188
5·0	95·0	1·699	5·56	0·327
0	100·0	1·74	4·17	0·420

According to Linde's rule,[42] $\Delta\rho/A = a\Delta Z^2 + b$ where $\Delta\rho/A$ is the increase in specific resistivity per atomic-% of solute, ΔZ is the difference in valence between solute and solvent atoms, and a and b are constants. This rule does not apply to solutions of metals in magnesium in concentrations of 0–4·4 at.-%. The specific resistivity of magnesium due to alloying increases linearly with alloying content and the ratio $\Delta\rho/A$ is lowest for solutes from Column 1 of the Periodic Table and highest for solutes from Column 4. The increase in specific resistivity per atomic-% of solute depends more significantly upon the Column of the Periodic Table to which the alloying element belongs than upon the period or row. Thus the same value of $\Delta\rho/A$ is obtained for lithium and silver additives, 0·75 × 10^{-6} ohm cm./at.-% and a similar value for cadmium.[43] The properties of magnesium–lithium alloys including their density, diamond pyramid hardness, tensile strength, plasticity, and strain-hardening, have been reviewed.[44] Lithium can be added to magnesium-base alloys in amounts up to 12% to improve the creep resistance at elevated temperatures.[45] The production of lithium–magnesium alloys by the electrolysis of molten lithium chloride using magnesium cathodes has been described.[46] Lithium–magnesium alloys containing 52–70% of magnesium may be used as electrodes for electrical systems; they have electropositive properties very close to those of lithium but are far less reactive with water.[47] By the addition of 0·05% of lithium, the ultimate tensile strength of commercial magnesium is increased from 30,000 to 40,000 lb. per square inch and the hardness and corrosion resistance are also increased, but the ductility is slightly reduced.[18] The properties of some magnesium–lithium alloys containing aluminium and zinc,[48] the effect of sodium contamination on these alloys[49] and the ageing characteristics of magnesium–lithium base alloys[50] have been discussed. Corrosion-resistant magnesium alloys containing 1·6% of manganese are improved by adding 2·0–2·75% of lithium. The mechanical properties are: tensile strength 12·35–11·0 tons/sq.in., elongation 14·5–22·5% in 2 in.; a reduction of 45·6% can take place at room temperature.[51] A cast, extruded and heat-treated magnesium-base alloy, composed of 6–12% of lithium, 16–25% of zinc, 1–20% of cadmium and the rest magnesium, exhibits high yield strength under compression loads.[52] Age-hardening of a magnesium–lithium alloy containing magnesium and lithium in the ratio of 5:1 to 10:1 and at least one of the metals zinc, 4–10%, cadmium 4–24%, silver 0–12%, aluminium 4–12%, and having a new crystal phase (θ, a face-centred cubic structure of lattice constant of 6·5–6·92 A.) involves heating at 400°–600° F. to dissolve the θ phase, quenching and reheating at 150°–300° F. to precipitate the θ phase.[53] The addition of lithium to magnesium–cerium alloys has little influence on creep behaviour.[54] The cladding of magnesium–lithium alloys with stainless steel, aluminium or other metals or alloys to produce an article with the high strength of the base alloy and corrosion resistance of the cladding metal is described by Jackson[55] and Frost.[56] Magnesium–lithium alloys containing 30–45% of lithium have an electrical conductivity, on a weight basis, at least 50% of that of copper, and a very low temperature coefficient of electrical resistance $\leq$ 10% that of copper. These alloys when coated with pure magnesium, to prevent atmospheric oxidation, may be used for electrical conductors. Redistilled magnesium, 60 lb., and high-grade lithium of low sodium content, 40 lb., are melted together in an iron crucible in a purified helium atmosphere. The resulting alloy is stirred thoroughly at 900°C., cooled to 750° and cast in a water-cooled iron mould in helium. The ingots are formed into strips and split into electric conductors for use in transformers. The strips are cleaned by mechanical abrasion under light oil, dipped in an N. solution of ethyl magnesium bromide in ether for 10 min., removed and washed with ether. The strips are then coated with pure magnesium of a thickness of about 0·0002 in.[57] A melting flux for magnesium–lithium alloys, which permits good separation of the flux from the metal during pouring, contains lithium bromide which increases the specific gravity of the flux. The following fluxes have been used: 3 parts of lithium bromide, and 1 part of lithium chloride, plus about 10% lithium fluoride, or 75% of lithium bromide and 25% of lithium chloride.[58] Lithium in magnesium–lithium alloys containing 12–13% Li may be determined to within 0·06% of the true value by internal-standard flame photometry.[59] It may also be determined by precipitation in saturated aqueous lithium chloride solution in the form of $LiNi(UO_2)_3,(C_2H_3O_2)_9,nH_2O$. The presence of Mg^{++}, Al^{+++}, Zn^{++}, if less than 10 mg., does not interfere with the determination of 0·1–1 mg. of lithium.[60] Determination of hydrogen in magnesium–lithium alloys is carried out by dissolving the sample in molten tin at 450°C., heating in a borosilicate tube, and measuring the volume of gas evolved. The sample must be protected from air while it is being weighed and loaded into the furnace.[61] Lithium, added to a magnesium base alloy, provides a sacrificial anode *i.e.* one which is more anodic than the normal cell anode, pure magnesium. The two are coupled together electrically and the cell anode becomes cathodic to the sacrificial anode; reactions which normally ensue on storage between the normal anode and the electrolyte are transferred to the sacrificial anode which becomes corroded. The shelf life of such cells is thus increased.[62]

The equilibrium diagram for calcium–lithium alloys has been described; the metals are completely miscible in the liquid state and on cooling a peritectic reaction occurs at 225°C. resulting in the formation of the compound Ca_2Li. This substance forms a eutectic with lithium which melts at 165°C.[63] The compound Li_2Ca has been prepared by melting the theoretical amounts of the metals in argon. Its structure is of the $MgZn_2$ type; the lattice constants are:[64] a 6·248 ± 0·008 A., c 10·23 ± 0·002 A. A process of electrolytic production of lithium-calcium alloys is described in which the anode is placed in the lower portion of a fused bath of lithium chloride and calcium chloride and the cathode in the upper portion of the bath.[65] Lithium–calcium alloys are used for purifying molten metals such as iron or steel,[66,67] copper or copper alloys[68] and nickel or its alloys.[69]

Lithium–calcium alloys when treated with hydrogen under the conditions described below, form solid solutions of the hydrides of lithium and calcium containing 1–50% of lithium hydride and not more than about 3% of calcium and lithium in their elemental forms. These solid solutions are capable of generating hydrogen for use where it would be inconvenient, expensive and sometimes prohibitive to carry hydrogen gas, and are easily shipped. Lithium–calcium

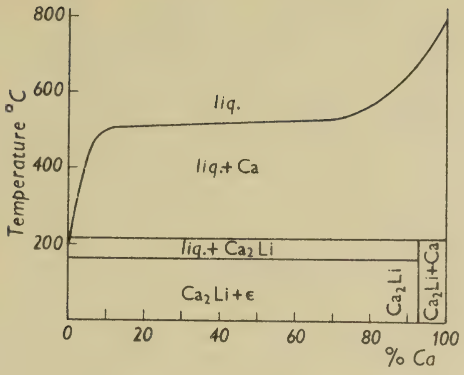

FIG. 5. EQUILIBRIUM DIAGRAM OF THE LITHIUM–CALCIUM SYSTEM.[63]

alloys containing 1, 5, 25 or 50% lithium are used in the form of ingots, 6 in. × 2 in. × 3 in.; they are charged into a reactor which is purged to remove air and gas-heated to about 400°C. Hydrogen is then admitted and the heating supply cut off; the heat of reaction causes the temperature to rise to about 900°C. for the 5% alloy, 1000–1100°C. for the 25% alloy and 1200°C. for the 50% alloy. Hydrogen is continuously supplied to maintain a gauge pressure of about 5 lb. The time of reaction is about 6, 5 and 3 hr. respectively for the 5%, 25% and 50% alloys; after the above times of reaction the hydrogen supply is cut off, the pot is allowed to cool and the product is broken in lumps about 1 in. or smaller. The 25 and 50% alloys yield a distinctly crystalline product. For the 1% alloy, the temperature must be at least 400°C. but not higher than 500°C. and the hydrogen pressure for the first four hours must be at 1 lb. gauge pressure and then raised to 5 lb. This reaction is completed in 12 hr.[70]

Fraenkel and Hahn, in their study of zinc-rich lithium alloys, found that the liquidus temperature decreases from the melting point of zinc to a eutectic point at 0·6% of lithium at 402°C. and then increases to 517°C. at 6% and further to a maximum at 519°C. at 6·2%, corresponding to the formula Li_2Zn_3. Zinc retains about 0·2% of lithium in solid solution and the compound Li_2Zn_3 forms a homogeneous phase with zinc up to a concentration of about 1·4% of lithium.[5,71] Zintl and Brauer prepared an alloy containing 48·7 atomic-% of lithium; it was finely crystalline and on removing the gray outer coating in an inert gas a copper-red surface was exposed. This compound, LiZn, was shown to have the NaTl structure (cf. Sect. XXVI) with a lattice constant 6·209 ± 0·005 A. and density 4·18: the number of atoms per unit cell was 16·3 as compared with 16 for the NaTl structure.[25] The complete phase diagram for the lithium–zinc system has been determined by Grube and Vosskühler and five series of solid solutions are shown, separated by heterogeneous fields. Alloys containing between 1·5 and 5 atomic-% of lithium solidified primarily as alpha-solid solution and a secondary separation then occurred at 403°C. of a eutectic, consisting of alpha- and beta-phases; the eutectic point was at slightly less than 5 atomic-% of lithium and the limits of the eutectic extended from 1·5 to 8·5 atomic-%. Between 8·5 and 20 atomic-%, beta-solid solution was formed directly from the melt. In the concentration range from 20 to 28 atomic-%, gamma-crystals separated out primarily and at 481°C. were transformed to beta-solid solution by a peritectic reaction with the rest of the melt according to the equation: melt + gamma ⇌ beta. All the alloys containing 24 to 26·5 atomic-% of lithium consisted on complete solidification of beta- and gamma-crystals. The time of arrest of the peritectic reaction could not be calculated because the primary and secondary crystallization temperatures were too close to each other. A further peritectic reaction occurred between 28·5 and 33 atomic-% of lithium: melt + delta ⇌ gamma. The delta-phase, which separated out directly from the melt between 33 and 50 atomic-%, was characterized by a maximum in the melting curve at 40 atomic-% of lithium at 520°C., and the melt solidified at a constant temperature with the formation of the compound, Li_2Zn_3; between 50 and 98 atomic-%, the molten eutectic crystallized out; from 50 to 95·5 atomic-% the delta-phase separated out primarily and the eutectic secondarily. The epsilon-phase crystallized out primarily between 95·5 and 98 atomic-% of lithium and a eutectic point was observed at 95·5 atomic-% at 161°C. An alloy containing 50 atomic-% of lithium showed a slight arrest at 157°C.; alloys with 98 to 100 atomic-% of lithium solidified to unsaturated epsilon-solid solution. The existence of the compound, Li_2Zn_3, was thus confirmed and a new compound, $LiZn_2$, formed from gamma′ and delta′ solid solutions at 93°C. was detected. The presence of a third compound, LiZn, described by Zintl and Brauer, could not be definitely established although it is probably the delta″-phase. The compound, Li_2Zn_3, which crystallizes out directly from the melt, forms with excess of lithium or zinc the delta-solid solution, and at 174°C. the compound is transformed and forms with the component metals delta′-solid solution on cooling.[5,72] An *X*-ray analysis of alloys prepared by Zintl and Schneider confirms the finding of Grube and Vosskühler that there are five intermediate solid solutions at room temperature. The beta′-phase, with about 10 atomic-% of lithium, has a close-packed hexagonal structure with lattice parameters *a* 2·782 A.; *c* 4·385 A.; *c*/*a*, 1·576. For the gamma′-phase, with about 28 atomic-% of lithium, the lattice parameters are: *a* 4·362; *c* 2·510 A., and *c*/*a* 0·575.[73] The constitution of the delta″-phase, LiZn, has already been described.[25] The binary eutectic of zinc with lithium has been found to be at 403·25°C. and 0·38% of lithium.[74,75] The addition of 0·05% of lithium improves zinc alloys in the same way as does magnesium but, because of the lower equivalent weight of lithium, a smaller amount is required. The presence of lithium in zinc appears to shorten the time required in galvanizing processes.[18] The effect of adding lithium to zinc alloys for constructional materials has been discussed.[76,78] Impurities in zinc, such as lead, tin and cadmium may be removed by the addition of lithium at temperatures between 540° and 60°C. to the molten zinc or zinc alloy. The lithium forms intermetallic compounds with the impurities, Li_7Pb_2, m.p. 726°C., Li_7Sn_2, m.p. 785°C., LiCd, m.p. 549°C. The compound formed with zinc is Li_2Zn_3, m.p. 520°C. The lithium is stirred in at a temperature above the melting points of the intermetallic compounds of the impurities; the temperature is then lowered so that it is above 520°C. and the mixture filtered.[79]

The addition of lithium to zinc–aluminium alloys retards the monotectoid transformation in ageing at room temperature and at 95°C.[80] Other references are given to the addition of lithium to zinc alloys.[81–83]

The oxidation rate of zinc is increased by the addition of lithium.[84]

In their investigation of the lithium–cadmium system of alloys containing 0–30% of lithium, Masing and Tammann suspected the presence of two compounds: $LiCd_2$, at 2·99% of lithium from an observed thermal effect at 356°C., and LiCd at 5·8% of lithium from a maximum setting point at 541°C. As the amounts of material used were small, there is some uncertainty about the temperatures marking the end of solidification.[5] By means of thermal analyses, electrical conductivity and linear expansion measurements, Grube, Vosskühler

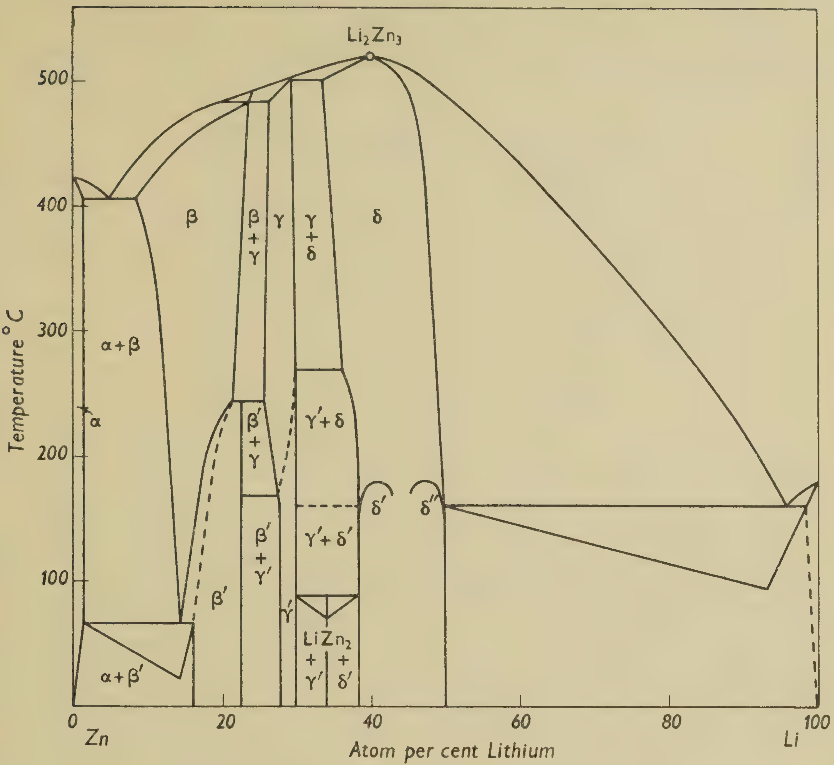

FIG. 6. EQUILIBRIUM DIAGRAM OF THE LITHIUM-ZINC SYSTEM.[72]

and Vogt observed five solid solutions separated by heterogeneous fields. The following compounds were detected: $LiCd_3$ at 2·02% of lithium at 370°C., LiCd at 5·8% and 541°C., and Li_3Cd at 15·63% and 272°C. The primary solid solutions, beta- and gamma-, on cooling to 370°C. and 272°C. were transformed respectively into the compounds $LiCd_3$ and Li_3Cd.[5,85] *X*-Ray analysis of the above system shows that the compound, LiCd, has a monometric structure of the CsCl type, the unit cell having *a* 3·32 A.[86] Zintl and Brauer, however, prepared an alloy containing 50·7 atomic-% of lithium, which was finely crystalline and copper-red in colour under its outer coating, and the structure was here shown to be of the NaTl (cf. Sect. XXVI) type with *a* 6·687 ± 0·003 A., density 5·20, with 15·9 atoms to the unit cell (16 for the NaTl structure).[25] The cubic lattice of the NaTl type for the compound, LiCd, is confirmed by Zintl and Schneider;[87] the lattice has *a* 4·250 A.[89] Baroni has discussed Zintl and Schneider's results.[88] According to Baroni the compound, $LiCd_3$, is also monometric with unit cell side *a* 8·62 A.,[86] but Zintl and Schneider give the following parameters: *a* 3·083 A.; *c* 4·889 A. and *c*/*a* 1·586.[89] The compound, Li_3Cd, found by thermal analysis, could not be identified by Baroni in his *X*-ray examination,[86] but Zintl and Schneider showed that it has a cubic lattice with *a* 4·250 A.[87,89] The beta-phase in the lithium–cadmium system exists only at high temperatures and probably has cubic symmetry. The beta′-phase corresponds in composition to the formula $LiCd_3$; the gamma-phase to LiCd and the gamma′-phase to Li_3Cd.[5,89] The modulus of elasticity of the hexagonal phase, $LiCd_3$, is similar to that of cadmium, *i.e.* about 6000 kg. per mm.^{2}; the modulus of elasticity of the cubic face-centred crystal, Li_3Cd, is only slightly higher than that of lithium. Between the phases $LiCd_3$ and Li_3Cd the modulus decreases linearly across the broad field of the LiCd phase.[90]

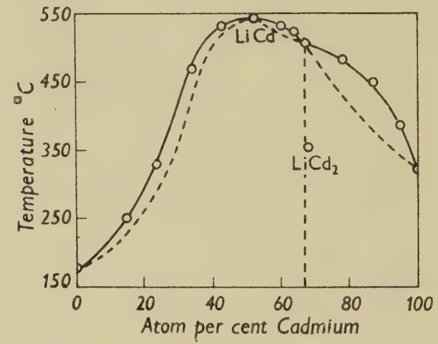

FIG. 7. EQUILIBRIUM DIAGRAM OF THE LITHIUM-CADMIUM SYSTEM.[85]

A phase diagram for lithium-mercury alloys containing 0·1 to 77·4% of lithium has been constructed by Grube and Wolf (see page 112); the existence of the compounds $LiHg_3$, $LiHg_2$, LiHg, Li_3Hg, found by Zukowsky[91] has been confirmed, and two more compounds have been detected, Li_2Hg and Li_6Hg. The compounds LiHg and Li_3Hg melt at 590° and 375°C. respectively; all the other compounds are formed by peritectic reaction and the decomposition temperatures of the following compounds are: $LiHg_3$, 235°C.; $LiHg_2$, 340°C.; Li_2Hg, 375°C. and Li_6Hg, 164°C.[92] Zintl and Brauer prepared an alloy containing 50·9 atomic-% of lithium and showed that this finely crystalline, greyish compound had the same structure as beta-brass with *a* 3·287 ± 0·005 A.[25] Zintl and Schneider have obtained a hexagonal structure for the compound $LiHg_3$ with *a* 6·240 A.; *c* 4·794 A.; *c/a*, 0·768; the unit cell contains 2 atoms of lithium and 6 of mercury. The compound Li_3Hg has a cubic structure with *a* 6·584 A., and there are 4 atoms of mercury and 12 of lithium per unit cell.[93]

The lithium-aluminium system has been studied by many workers. The amount of lithium held in alpha-solid solution has been quoted as 3%,[94] 2·2% at room temperature and 3·5% at 598°C.,[5,95] 3·5% at 590°C.,[5,96] 7 to 8 atomic-% at room temperature[97] and 5·2, 4·44, 3·61, 2·55, 1·87, 1·67 and 0·88% respectively at 600°, 579°, 548°, 501°, 433°, 400° and 223°C.[16,98] The eutectic point between the alpha- and beta-phases has been reported to lie at 590°C. and 7% of lithium,[94] at 598°C. and 7·8%,[95] at 590°C. and 7·3%,[5,96] at 600°C. and 30 atomic-% of lithium[97] and at 602°C. and 26·3 atomic-% of lithium.[99,100] Kipnis and Rogelberg have used the Shreder[101] equation:

$$d \ln \chi/dT = \phi/RT^2$$

to verify the course of the solubility curves of binary metallic systems. Regardless of whether or not the indicated values correspond to the actual values of the heats of solution, it is possible from the nature of the variation of ϕ with T to judge the correctness of the solubility curve, since $\phi = f(T)$.

The relation between the heat of solution and temperature is shown in Fig. 8 for the system aluminium-lithium.[102]

The existence of a compound, LiAl, at 20·46% of lithium with a freezing point at about 720°C. was observed by Müller[5,96] and its presence was confirmed by Grube, Mohr and Breuning[97] and by other workers, who found that it melted

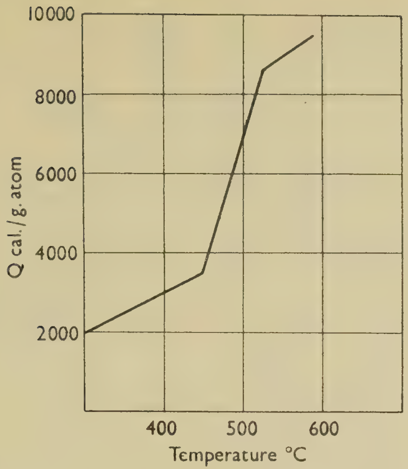

FIG. 8. RELATION BETWEEN HEAT OF SOLUTION AND TEMPERATURE FOR LITHIUM–ALUMINIUM.

congruently without decomposition at 718°C.[99,100] The compound, LiAl, forms with excess of beta-solid solution a homogeneous region which extends at 521°C. from 50 to 56 atomic-% of lithium; the existence of the crystalline compound, Li_2Al, formed at 521°C. by peritectic reaction between beta-solid solution and melt has been observed[97] and its presence was confirmed by later workers at 523°C.[99 100] A hitherto unknown eutectic between the compound Li_2Al (gamma-phase) and lithium (delta-phase) is shown to exist at 94 atomic-% of lithium at 170·6°.[99] An *X*-ray investigation of lithium-aluminium alloys containing up to 20·5% of lithium showed two phases, alpha- and beta-; the alpha-phase displayed no difference in lattice parameters from pure aluminium.[103] Vosskühler, however, found that the addition of lithium to aluminium, in the region of 0·88 to 4·44% of lithium, caused a slight contraction in the lattice, which decreased from 4·040 to 4·037 A. and then remained constant.[98] Others confirm the contraction of the aluminium lattice by solution of lithium and give the following values, measured at 25°C.: pure aluminium, 4·0413 kx; alloys with 0·91, 1·29 and 1·93% of lithium, 4·0396, 4·0392, 4·0381 kx respectively. If the lattice spacing/composition curve is extrapolated to 100% of lithium, the lattice spacing then refers to a hypothetical face-centred cubic modification of the solute, and the corresponding closest distance of approach of the atoms is the apparent atomic diameter of lithium when in solution in aluminium. The apparent atomic diameter is found to be 2·82; the atomic diameter for lithium is 3·03 kx.[104] According to Pastorello, the compound, LiAl, has a lattice constant of 3·23 A., resembling that of the compound LiAg;[24] later workers state that the compound LiAl has a body-centred cubic lattice of the NaTl type with 16 atoms per unit cell, and a 6·37 kx[103] or a 6·36 A.[105] The radius of both atoms is 1·38 A.[105] The abnormal results of measurements of the irreversible electrode potential of aluminium–lithium alloys (containing up to 13 vol.-% of lithium) in 0·1 N-hydrochloric acid cannot arise from the presence of a protective film and hence must be attributed to a change in the electrochemical behaviour of lithium in solid solution with aluminium.[106] The elastic modulus of aluminium is increased by the addition of lithium in the alpha solid solution region and in the heterogeneous field next to it; for the compound, LiAl, the modulus is greater than would be expected from the law of mixtures.[90] Alloys containing more than 4% of lithium were observed to be readily corroded and those with more than 10% to oxidize rapidly in air and decompose water with

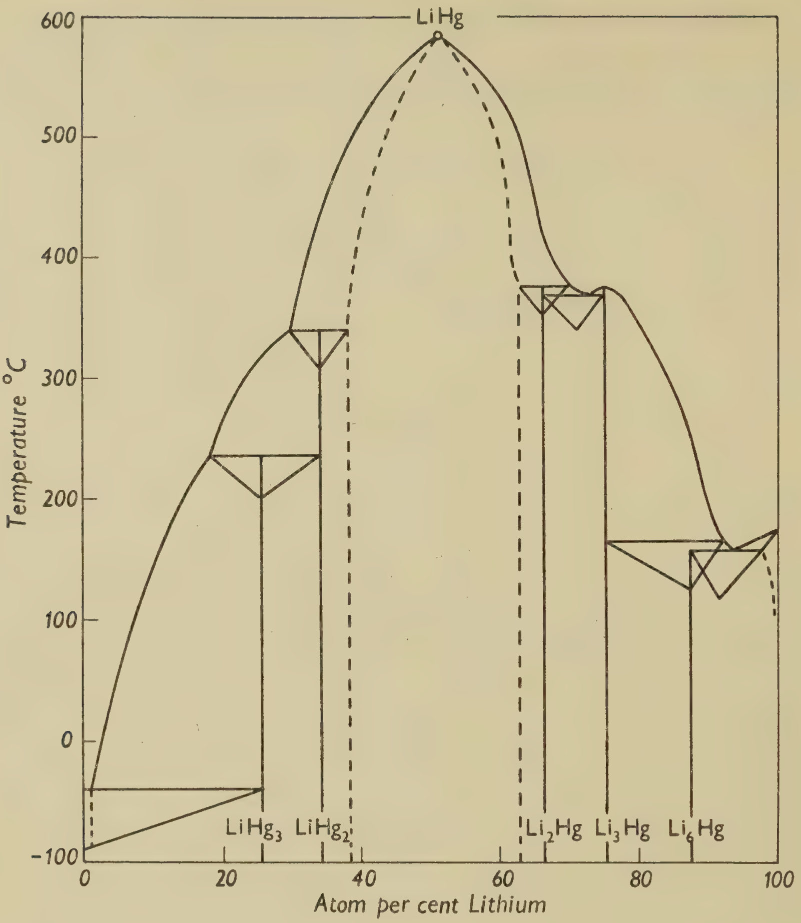

FIG. 9. EQUILIBRIUM DIAGRAM OF THE LITHIUM-MERCURY SYSTEM.[92]

the evolution of hydrogen.[95] It has been stated that alloys containing up to 5·2% of lithium are only slightly corroded after exposure for ten months to 5% sodium chloride solution. The lower resistance to attack found in alloys with larger amounts of lithium is considered to be due to the presence of undissolved LiAl.[98] Kroll, however, queries the stability of alloys containing 5·2% of lithium in view of the poor results obtained with alloys of the 'Scleron' type.[107] It has been shown that the aluminium-lithium alloy which exhibits the maximum resistance to corrosion by hydrochloric acid and sodium chloride solutions is one containing 2·94 atomic-% of lithium; a crystalline chemical compound is formed on the surface of such an alloy.[108] The addition of lithium to aluminium increases the Brinell hardness of annealed specimens; the increase is rapid between 2 and 3·5% of lithium and slower above 3·5%. On a weight-% basis lithium produces a greater increase in hardness than does magnesium but on an atomic basis, the reverse is true. The effect of mechanical and heat treatment has also been investigated; annealing cold-worked specimens at 500°C., quenching and ageing at room temperature produced a 16% increase in hardness. Ageing at 100°C. made no appreciable difference while at

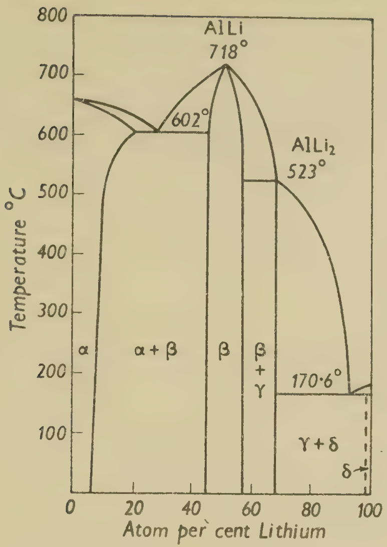

FIG. 10. EQUILIBRIUM DIAGRAM OF THE LITHIUM–ALUMINIUM SYSTEM.[99]

200° C. the beneficial result was lost. A higher Brinell value for the cast than for the worked material was obtained by prolonging the annealing time previous to quenching.[95,98] The importance of silicon in the mechanical improvement of aluminium with lithium has been studied; a 50% increase in hardness was produced when the ratio of lithium to silicon corresponded to the compound Li_3Si; it is suggested that because the solubility of the silicide decreases as the temperature is reduced, the system is converted to a metastable state on quenching and contains the silicide in supersaturated solution. On ageing, the compound Li_3Si separates out in a highly disperse form producing the increased hardness; if ageing is carried out at 200°C. or higher temperatures, the silicide separates out in a coarser form, no longer increasing the hardness.[109] A number of other publications dealing with the improvement of aluminium or its alloys by the addition of lithium are cited.[110–122] Some aluminium-base alloys containing lithium and which can be heat treated, or age-hardened, and possess high strength and other good mechanical properties in conjunction with low density are described. These alloys contain, as cast, 0·2–5% of lithium and not more than, and generally less than, 0·008% of sodium. The deleterious effect of sodium is shown in Table IV, which gives the properties of two alloys, chill-cast under identical conditions, both containing additions of 3·5% of different grades of lithium.

TABLE IV.- EFFECT OF SODIUM ON MECHANICAL PROPERTIES OF ALUMINIUM-BASE LITHIUM ALLOYS

Nature of Li	Na Content by Analysis	Ultimate Tensile Strength Tons/sq.in.	Elongation %
A. Low Na content < 0·02%	0·004%	17·0	0·5
B. Na content approx. 0·35%	0·01%	8·4	Nil

A less obvious effect of sodium when present in amounts which may not affect the properties of the alloy 'as cast' or 'as wrought', is the interference with the response to heat treatment. The alloy is liable to crack during quenching or an embrittling effect is produced.(see Table V).

TABLE V.- EFFECT OF HEAT-TREATMENT ON ALUMINIUM-BASE ALLOYS CONTAINING LITHIUM AND SODIUM

Alloy prepared from:	Analysis Li %	Analysis Na %	Mechanical Properties: As Chill-Cast U.T.S. T/sq.in.	As Chill-Cast Elong. %	Heat Treated(a) U.T.S. T/sq.in.	Heat Treated(a) Elong. %	Heat Treated(b) U.T.S. T/sq.in.	Heat Treated(b) Elong. %

D. Less pure materials	3·14	0·006	15·25	Nil	Cracked & fell to pieces during machining		11·2	Nil

Heat treatment (a) 24 hr. at 510°C., water quenched (cold), 48 hr. at 175°C.
Heat treatment (b) 24 hr. at 510°C., water quenched (hot), 48 hr. at 175°C.

The limit of sodium in a heat-treatable, chill cast alloy containing an addition of 3·5% of lithium is 0·005% of sodium, but 0·003% is recommended. The aluminium itself has a sodium content of 0·003–0·005% and may contribute sufficient sodium to make the alloy unsuitable for some purposes.

Ordinary grade lithium contains about 0·35% of sodium; lithium containing less than 0·02% can generally be used with good results.

If both metals contain too much sodium they may be melted directly together under a flux capable of removing sodium. Halides can be used singly or together for this purpose but to avoid removal of lithium from the melt, and contamination of the metals, it is necessary that halides reducible by lithium such as sodium chloride or magnesium chloride should be present in only a small proportion of the mixed flux, or better still, excluded altogether. Good results have been obtained by the use of refined lithium chloride as a melting flux, and where a lower melting point is desired, a eutectic mixture of lithium chloride and lithium fluoride may be used.

Table VI gives results showing the effect of alloying procedure.

TABLE VI.- TENSILE PROPERTIES OF CHILL-CAST ALLOYS CONTAINING ADDITIONS OF ABOUT 3·2% Li AND 0·15% Ti

Analysis Li %	Analysis Na %	Alloying Procedure	As Cast U.T.S T/sq.in.	As Cast Elong. %	Heat Treated U.T.S. T/sq.in.	Heat Treated Elong. %

The properties of a variety of cast and wrought aluminium-base alloys containing additions of other elements as well as lithium are also given.[121]

Aluminium alloys containing 0·01–1% of lithium, 13–20% of silicon with or without copper up to 18%, silver up to 10% and/or magnesium up to 5%, the remainder being aluminium, can be tempered and used for making pistons and other machine parts.[122] Among such alloys 'Scleron' is of special interest because its physical properties resemble those of mild steel or brass; its tensile strength, elastic properties and hardness are reported to be superior to those of 'duralumin'. A typical composition of 'Scleron' is: 83, Al; 12, Zn; 2, Cu; 0·5–1, Mn; 0·5, Fe; 0·5, Si; 0·1, Li.[18] The use of lithium to improve metallic surfaces has been described: aluminium–lithium wire containing 6·69% of lithium is heated at 590°C. in a bath containing 75% of sodium dichromate and 25% of potassium dichromate; lithium diffuses out to the surface of the wire producing a homogeneous aluminium–lithium coating, resistant to corrosion.[123] Methods for the introduction of lithium into aluminium or its alloys have been described.[124,125]

The compound with gallium, LiGa, containing 9·05% of lithium, has the same structure as the compound NaTl; the side of the lattice, *a*, is 6·195 ± 0·007 A.[5,25] A lithium–gallium alloy of composition Li_3Ga has been obtained by melting the metals together in argon at 600°.[126]

The complete phase diagram for the lithium–indium system has been constructed and only one compound, LiIn, has been detected. It has a bright steel-blue colour, is very brittle and melts without decomposition at 625°C.[5,17,127,128] This compound has the NaTl structure and the side of the lattice, *a*, is 6·786 ± 0·005 A.[25] Lithium is used to activate indium sulphide phosphors.[129]

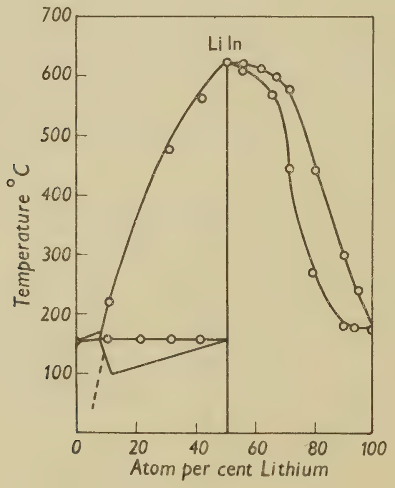

FIG. 11. EQUILIBRIUM DIAGRAM OF THE LITHIUM–INDIUM SYSTEM.[127]

The following intermetallic compounds have been detected in the lithium–thallium system: LiTl, Li_2Tl, Li_5Tl_2, Li_3Tl and Li_4Tl; the last four compounds vary in colour from rose to violet. The compounds LiTl, Li_5Tl_2 and Li_3Tl melt without decomposition; the others decompose on melting and the upper existence limit for both the compounds Li_2Tl and Li_4Tl lies at 381°C. The complete phase diagram has been constructed.[130] Zintl and Brauer have examined the structure of the compound, LiTl, which has a greyish colour, and have shown it to possess the beta-brass structure with *a* 3·424 ± 0·003 A., and density 8·56, the number of atoms per unit cell being 1·95.[5,25]

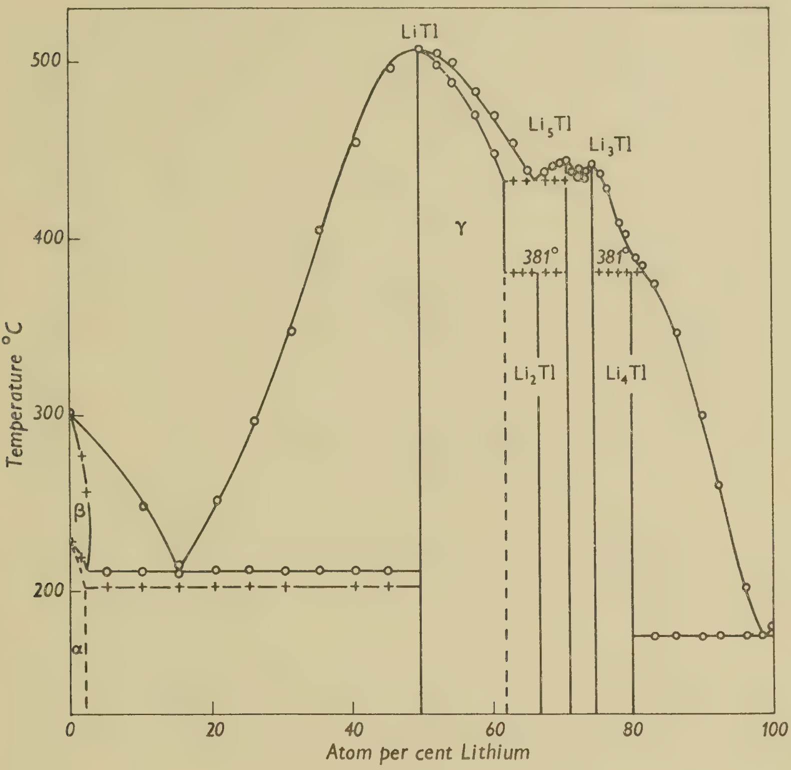

FIG. 12. EQUILIBRIUM DIAGRAM OF THE LITHIUM-THALLIUM SYSTEM.[130]

By thermal analysis and microscopical examination of lithium-tin alloys, Masing and Tammann detected the compounds Li_4Sn, Li_3Sn_2 and Li_2Sn_5 at 81·05, 91·94 and 97·72% of tin respectively. A eutectic point at 175°C. was observed, the eutectic mixture consisting of lithium and Li_4Sn.[4,5] The presence of the compounds Li_4Sn, m.p. 684°C.; Li_3Sn_2, m.p. 483°C., $LiSn_4$ and of three eutectics, m.p. 458°C., 320°C. and 214°C., containing respectively 35, 58 and 94 atomic-% of tin, were observed by Baroni. *X*-Ray analysis indicated the presence of the first two compounds but the compound $LiSn_4$, which decomposes on cooling, was not identified. The complete phase diagram is given.[131] In their attempt to prepare the compound LiSn, Zintl and Brauer obtained alloys which were not homogeneous.[25] The following intermetallic compounds have been found by Grube and Meyer: $LiSn_2$, upper existence limit 326°C.; LiSn, m.p. 485°C.; Li_2Sn, upper existence limit 502°C.; Li_5Sn_2, upper existence limit 720°C.; Li_7Sn_2, m.p. 783°C.; and Li_4Sn, m.p. 765°C. The compound LiSn forms a solid solution with excess of lithium; the compound Li_7Sn_2 forms alpha-solid solution with excess tin; the compounds LiSn, Li_7Sn_2 and Li_4Sn are formed by peritectic reactions. Pure tin does not hold

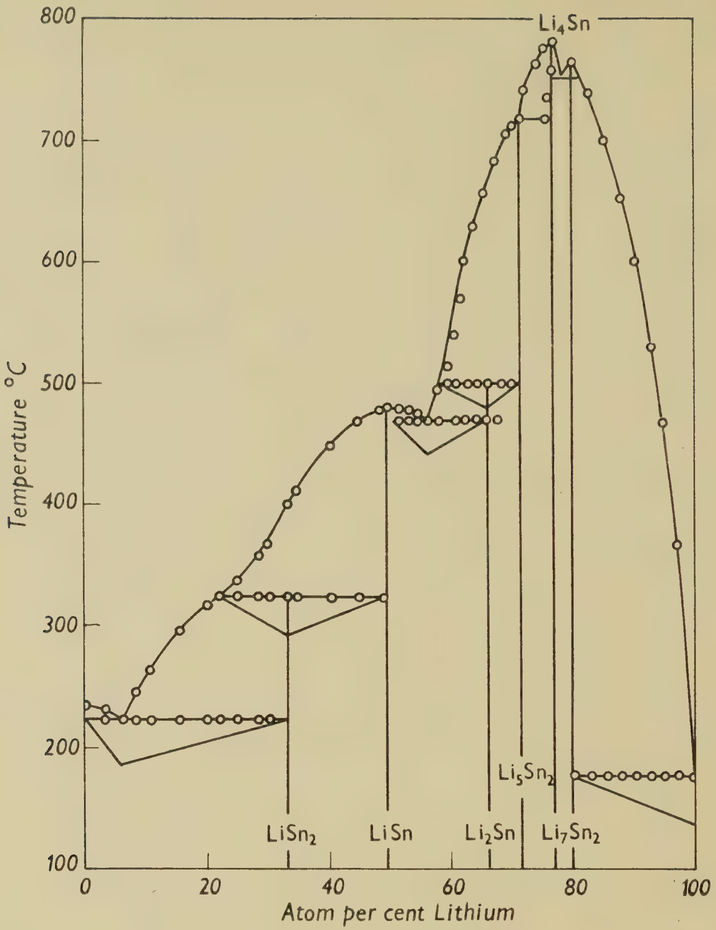

FIG. 13. EQUILIBRIUM DIAGRAM OF THE LITHIUM–TIN SYSTEM.[132]

any appreciable amount of lithium in solid solution;[132] the solid solubility of lithium in tin at 200°C. is less than 0·1 atomic-% of lithium.[133] The average pressure coefficients of electrical resistance up to 12,000 kg. per sq. cm. have been measured at 30°C. and 75°C.;[134,135] selected values are given in Table X.

TABLE X.- PRESSURE COEFFICIENTS OF ELECTRICAL RESISTANCE OF LITHIUM–TIN ALLOYS

Atomic-% Sn	$(1/R_0)(\Delta R/\Delta P)$ 30°	$(1/R_0)(\Delta R/\Delta P)$ 75°

100	$-0{\cdot}0_59295$	$-0{\cdot}0_59434$

More recently, Bridgman,[41] has examined the effect of pressures up to 30,000 kg./cm.^{2} on the electrical resistance of lithium–tin alloys containing 0–40 at.-% of tin, and included in his specimens Ufford's samples[134,135] which had been kept for 27 years under 'nujol'.

TABLE XI.- LITHIUM–TIN SYSTEM: EFFECT OF TEMPERATURE AND PRESSURE ON ELECTRICAL RESISTIVITY

In the above Table densities refer to room temperatures, ρ_{oo} to specific resistance at 0°C. and atmospheric pressure. The temperature coefficient of resistance, measured between room temperature and 0°C., is expressed as the fractional change of resistance per degree in terms of resistance at 0°C. as unity.

The approximate constancy of both temperature coefficient and pressure effect from pure lithium up to 10% of tin, would seem to indicate the very small solubility in pure lithium. Up to 10% of tin the system is almost entirely a mechanical mixture, and if Hansen's diagram is correct this would be a mechanical mixture of pure lithium with the compound Li_4Sn. There would appear to be still another phase not known to Hansen, between 10 and 20 at.-% of tin. The composition 60Li–40Sn corresponds to the compound Li_3Sn_2 shown by Hansen.

The solid solubility of lithium in lead has been given as 0·04 to 0·09%,[136] and 0·03 to 0·1%[18] of lithium. A eutectic is formed at 231°C. and 0·65% of lithium, consisting of the above solid solution and a compound, Pb_3Li_2; beyond this point, the liquidus curve rises to 470°C. at 2·15% where the compound Pb_3Li_2 begins to crystallize out. Alloys containing up to 2·15% of lithium are stable in air; those richer in lithium decompose rapidly.[136] The complete phase diagram has been constructed and the following intermetallic compounds found: LiPb, m.p. 482°C.; Li_7Pb_2, m.p. 726°C. (both of these compounds are formed by peritectic reactions); Li_5Pb_2, upper existence limit, 642°C.; Li_3Pb, upper existence limit, 658°C.; and Li_4Pb, upper existence limit, 648°C. Lead absorbs the compound LiPb in a narrow concentration region with the formation of alpha-solid solution; with excess of lithium, the compound LiPb forms beta-solid solution and the compound Li_7Pb_2 forms gamma-solid solution.[137] According to Rollier and Arreghini, only one compound, $Li_{10}Pb_3$, exists in the region previously shown to contain Li_3Pb, Li_7Pb_2 and Li_4Pb. The compound $Li_{10}Pb_3$ crystallizes in the cubic system with *a* 10·082 kx and has a structure similar to that of gamma-brass.[138] The com-

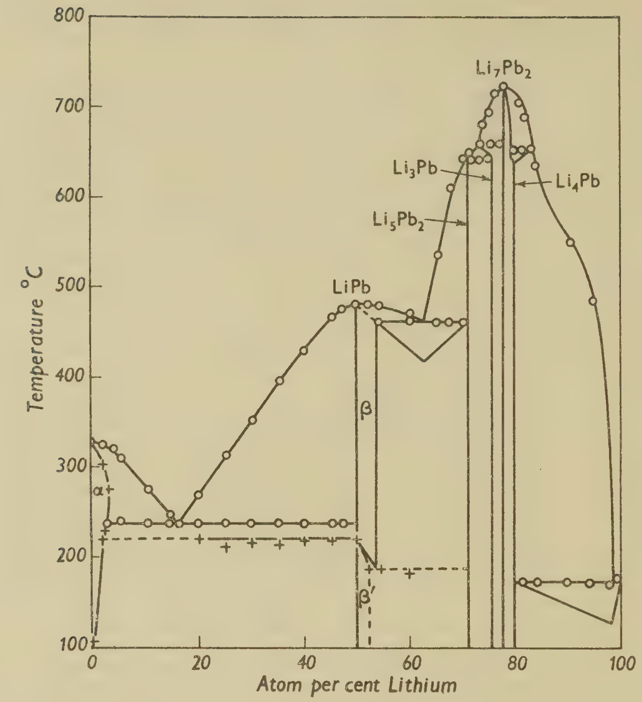

FIG. 14. EQUILIBRIUM DIAGRAM OF THE LITHIUM-LEAD SYSTEM.[137]

pound LiPb exists in two forms with a transition temperature at 214°C. Between 50° and 200°C. the alloy has a negative temperature coefficient of electrical resistance and resistance/temperature curves show an abrupt transition from abnormal to normal behaviour at 186°C. to 214°C., depending upon the composition of the alloy. Above 214°C. the coefficient is positive.[137] Wilson has measured the electrical resistance of an alloy containing 55·6 atomic-% of lithium over a wider range of temperatures and found that at temperatures below 50°C. the alloy behaves as a normal metal. Between 50° and 200°C. the effect described by Grube and Klaiber is observed, resulting in a negative temperature coefficient of resistance; above 200°C. the coefficient becomes positive again. Similar results are obtained at pressures of 5000 kg. per $cm.^2$ and 10,000 kg. per $cm.^2$, but the transition temperature is lowered by the increase of pressure. This beta'-beta transformation probably takes place gradually on heating, and a phase of abnormally high energy and entropy content is changed to one of a more normal character. X-Ray methods indicate that the transition is accompanied by movement of the lithium atoms in the lattice to more orderly positions. For an alloy containing 55·6 atomic-% of lithium, the lead atoms are arranged on a body-centred cubic lattice in both the beta'- and beta-phases; the lattice constant is 5·015 A. and the density 6·06. It is suggested that at 0°C. the lithium atoms are more or less irregularly scattered among the many equivalent positions in the lattice, the irregularity giving rise to the abnormally high entropy and the high value of electrical resistance. As room temperature is approached a slight distortion of the lead lattice takes place and the lithium atoms arrange themselves in more ordered positions. The process of distortion and rearrangement continues as the melting point of lithium is approached, culminating in a complete transition to an orderly arrangement at the critical point. The effect of pressure on the beta′-phase is to enhance the distortion and rearrangement process.[139] Nowotny has also examined two alloys near the equiatomic ratio (3·1 and 3·4% of lithium) and found that the beta′-phase, stable at room temperature, is isomorphous with beta-brass and has a lattice constant of 3·522 A. No evidence is found by *X*-ray methods for a disordered high temperature modification, beta-phase, and at 260°C. lines of the beta′-phase are found; the weak interference lines observed are considered to be due to traces of oxide. The *X*-ray density of the beta′-phase is 8·09.[140] The intermetallic compound, LiPb, has been examined also by Gundermann; it crystallizes in a similar way to cæsium chloride and is built up of two simple cubic structures; the author concludes from his results that the compound has a kind of salt-like structure and points out that the radius ratio for Pb^+ and Li^-, 0·74, would be the theoretical value for the cæsium chloride type of structure.[141] Dehlinger and Nowotny have discussed the results of Gundermann.[142] In an application of type models of the electron theory to the crystal chemistry of alloys, the electron arrangements for the lithium-lead system have been tabulated.[143] Alloys consisting mainly of lead are hardened by the addition of about 1 to 3% of lithium; with 1% of lithium a Brinell hardness of 17 is obtained, with 2% a hardness of 25.[144] The addition of 0·07% of lithium increases the hardness of lead to the same extent as does 0·1% of calcium, the resulting hardness in the cast state being 18·5 kg. per mm². A diagram has been constructed to show the effect of increase in lithium content from 0·01 to 0·10% on the cast hardness of lead.[145] The tensile strength, modulus of elasticity and hardness of lead are increased by the addition of 0·05% of lithium which produces a fine grain structure and retards crystallization. Lithium has also been used in lead-base, alkali-hardened bearing alloy, *i.e.* 'B'-metal, to which it imparts hardness, especially at elevated temperatures, high resistance to deformation and satisfactory wearing qualities.[18] 'B'-metal, consisting of lithium 0·04, calcium 0·69, sodium 0·62 and aluminium 0·02% with the remainder lead, has been used extensively because of its good frictional properties, but after long service at elevated temperatures some of the hardness is lost as also are some of the alloying metals on melting and casting. Reduction of lithium and sodium to the limit of the alpha-solubility eliminates the loss of hardness for ordinary service temperatures and decreases the loss of alloying elements on melting. Hardness values for a lead-lithium alloy containing 0·04% of lithium, which is slightly in excess of the solid solubility of lithium, and for 'B'-metal are given.[146] Lithium is introduced into lead or lead alloys at a temperature not substantially above 370°C.;[147] it is also used in lead-containing bearing alloys to give sufficiently dense and homogeneous alloys and to effect deoxidation, desulphurizing and outgassing of remelted alloys; means of adding the lithium are described and many references given.[148]

The modulus of elasticity of lead-lithium alloys has been measured from the lead side up to the crystalline compound LiPb; the modulus is first raised by the addition of lithium but decreases in the heterogeneous region. For the compound LiPb the modulus is smaller than would be expected from the rule of mixtures.[90] The density of lithium-lead alloy with 38 at.-% of lithium is 8·19 at 400°C.[149]

Lithium-antimony surfaces are particularly suitable for use in scintillation counters because of their low thermionic emission. The spectral characteristics of lithium-antimony photoelectric cathodes have been determined.[150,151] The addition of lithium to lead-antimony bearing alloys improves their physical properties.[152]

The phase diagram for lithium-bismuth alloys has been determined by thermal analysis and electrical conductivity measurements. The compound, Li_3Bi, m.p. 1145°C., is stable at this temperature; at 415°C. a peritectic reaction occurs with the formation of the compound LiBi, which exists in two forms, alpha and beta, with a transition point at 400°C. No solid solutions are formed. A eutectic between lithium and alpha-LiBi appears at 243°C. and 14 atomic-% of lithium. Between 35 and 37 atomic-% of lithium, beta-LiBi appears only as a primary material. The eutectic, LiBi-Li, appears at 175°C. at 97·5 atomic-% of lithium.[153] The compound, Li_3Bi has a cubic structure with a 6·708 A. and with 16 atoms per unit cell; alpha-LiBi has a tetragonal space-centred structure with a 3·361 A., c 4·247 A. and c/a, 1·264.[5,154] The tetragonal space-centred crystalline compound LiBi has a slightly lower modulus of elasticity than would be expected from the rule of mixtures.[90] Conditions of stability of tetragonal binary lattices are calculated with the help of an interaction energy ϕ of the type, $\phi = (mn\phi_0)\ \{(-1/m)(ro/r)^m + (1/n)(ro/r)^n\}/(n-m)$ where ϕ_0, r_0, m and n are parameters. The dimensions of the unit cell are $r_1 = r_2 \neq r_3$ with $(r_3/r_1) = \gamma$. The interval $\sqrt{1/2} \leq \gamma \leq \sqrt{2}$ is considered. A relation is found between γ^2 and a geometrical parameter a which is identified with the ratio of the radii of the lattice constituents. For LiBr, $\gamma^2 = 1{\cdot}598$ and $a = 0{\cdot}86$. The experimental data are in perfect agreement with the values found on the theoretical curve relating a and γ^2. The Goldschmidt-Bragg model of closed-packed spheres fails in this case.[155]

The alloy, LiBi, prepared from lithium freed from sodium and potassium by partial distillation in a vacuum, is transformed into the superconducting state at 2·4–2·5°K. The alloy $BiLi_3$ is not superconducting.[156] The thorium C isotope of bismuth has been used as an indicator in lithium-bismuth melts and no intermetallic order phenomenon has been noted.[157]

Lithium is insoluble in solid iron; nor does iron dissolve in liquid lithium.[5] When cast iron is treated with lithium the specific gravity of the iron is increased, the tensile strength and hardness are markedly improved and the treated iron can be more easily machined; the graphite in the iron is broken up into small particles uniformly dispersed throughout the metal and in the case of low-carbon grey iron the graphitic carbon is changed to carbide. Examples are given showing the improved properties of the lithium treated iron. A considerable increase in elastic limit is obtained when carbon steels are treated with lithium. The addition of a lithium alloy to stainless steel, 'Nirosta' KA_2, Allegheny metal, improves its fluidity so that it can be poured at a temperature at which the untreated metal is sluggish; the metal shrinks more uniformly instead of showing the 'centre pipe' effect; its tensile strength, Brinell hardness and elongation are increased and the non-metallic impurities are appreciably less and are more finely divided and uniformly distributed within the crystal and not along the grain boundaries. The metal is also freed from gases and its specific gravity increased; the treated steel has a higher resistance to corrosion and better polishing qualities. Other chrome-nickel steels behave in the same way.[18] The use of lithium in the production of nodular iron has been described.[158-167] Roos critically reviews the solidification process of ordinary and nodular cast irons and attributes the formation of spheroidal graphite in the latter to the existence of a dense α-allotrope, the formation of which is enhanced by lithium and magnesium. These elements increase the diffusion rate of carbon.[168]

The elastic limit, tensile strength, elongation and fluidity of nickel and its alloys are improved by treatment with lithium; one of the most harmful impurities in nickel is sulphur for which lithium has a high affinity.[18] The nickel in '304' stainless steel is leached from the surface and grainboundaries when a test piece is exposed to the action of lithium for forty hours at 1000°C. After 400 hours, the removal of nickel occurs to a considerable depth and cavities are visible in photomicrographs of the test specimen; this is a case of selective solution, and as a consequence of the reduced nickel content the face-centred cubic phase (austenitic) is rendered unstable and transformation to the body-centred cubic phase (ferritic) probably occurs.[169] The method of introducing lithium to nickel-rich alloys, such as nickel bronzes, and its effect on their physical properties have been described and many references are given.[148,170] Lithium–nickel alloys are improved by heating to high temperatures, rapidly cooling and subjecting to mechanical working at low temperatures.[171]

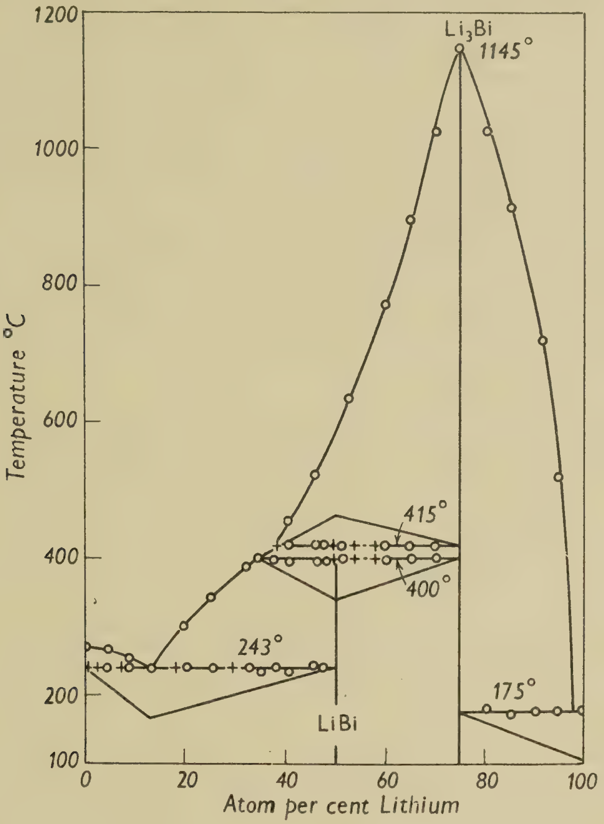

FIG. 15. EQUILIBRIUM DIAGRAM OF THE LITHIUM–BISMUTH SYSTEM.[153,169]

The addition of 0·02–1·0% of lithium to zirconium permits a quiet arc to be struck and maintained at 15–40 V. and 800–1800 amp., depending upon the electrode size. Argon is preferred as an inert atmosphere because it ionizes and assists the volatile metal in maintaining a steady arc.[172]

The tertiary system, magnesium-silver-lithium, has been investigated; the solubility of silver in magnesium is slightly increased by the presence of lithium whereas the solubility of lithium in magnesium is greatly reduced by the presence of silver at 421°C. The region of the alpha-solid solution is very much smaller at 321°C. than at 421°C. and the isothermal at 205°C.

shows how greatly the extent of the primary solid solution has narrowed at this temperature; very little silver can be held in solid solution at 205°C. As much as 13 atomic-% of lithium can be introduced into magnesium-silver alloys without taking the resultant alloy outside the (alpha plus Mg_3Ag) region. Alloys containing 26–30 atomic-% of lithium in the homogeneous beta-phase melt above 580°C. and, having a body-centred cubic structure, offer the possibility of ductile alloys lighter than magnesium. Preliminary experiments on corrosion have shown that alloys consisting of a few atomic-% of silver and up to 20 atomic-% of lithium show no obvious signs of corrosion after exposure to a domestic atmosphere for five months; alloys with 15 atomic-% of lithium with and without the addition of 1 atomic-% of silver or of silver and aluminium are only slightly tarnished on heating at 300°C. for 20 hours; they do not crumble to powder but appreciable quantities of a black powder are formed. These alloys cannot, however, be expected to resist salt-water corrosion.[173] The magnesium-lithium-silver system has been re-investigated more recently by Freeth and Rayner, particularly at the (alpha + beta)/beta phase boundary at temperatures between 208° and 500°C. The ternary beta-phase enters into equilibrium with alpha-phase, Mg_3Ag and MgAg; the lithium-rich corner of the alpha + beta + Mg_3Ag phase triangle occurs at the following composition for the temperatures studied:-

208°C. 4·5 atomic-% of silver; 25·5 atomic-% of lithium
305°C. 10·0 atomic-% of silver; 20·3 atomic-% of lithium
410°C. 14·3 atomic-% of silver; 12·5 atomic-% of lithium

At 495°C., beta-phase and liquid co-exist and experiments at 500°C. indicate that approximately 20 atomic-% of silver dissolves in the beta-phase at this temperature. A wide range of solution of lithium in the MgAg phase is also indicated.[37]

The ternary system, aluminium-magnesium-lithium, has also been studied and it has been shown that only one ternary compound, phase *X*, which has a composition approximating to Al_2MgLi, exists; it decomposes before melting into solid solutions. Ten phases are found in the system, nine being formed by primary crystallization since phase III forms IV in the solid state. Phases I, V and VII are solid solutions based on aluminium, magnesium and lithium respectively. The remaining phases, except *X*, are solid solutions based on binary intermediate phases. There are two ternary eutectics, one consisting of the phases V, VI and X at 419°C. and one involving VI, VII and VIII at less than 170°C. There are six transition points: (1) X + liquid → VI, 472°C.; (2) IX + liquid → X, 498°C.; (3) IV + liquid → X, 422°C.; (4) IX + liquid → X, 434°C.; (5) IX + liquid → VIII; (6) IV + liquid → II. Some of the phases rich in low-melting lithium have high melting temperatures.[174,175] The close-packed hexagonal structure of magnesium is converted to a ductile, malleable body-centred cubic lattice by the addition of lithium in excess of 10%, and the density of magnesium and magnesium-base alloys is decreased by the addition of lithium. The magnesium-rich corner of the 375°, 200° and 100°C. isothermals of the magnesium–aluminium–lithium system has been examined by metallographic and *X*-ray diffraction studies and the following results obtained. The phases in this corner are the magnesium-rich alpha solid solution, the lithium-rich beta solid solution, and the binary compounds $Mg_{17}Al_{12}$ and AlLi. The alpha and beta solid solutions are widely different in etching characteristics. The lithium-rich solid solution is very reactive chemically and even a rinse in ordinary tap water produces a distinctive brown film; the magnesium-rich solid solution remains unattacked. Typical structures of the various alloys are illustrated and *X*-ray diffraction patterns for each of the four phases agree with published data, and with patterns obtained from laboratory melts with synthetic compositions corresponding to the theoretical composition of each phase. Additional lines, usually very faint, are found on occasions and these could be attributed to nitrides or carbonates. Four of the additional lines are more intense and occur frequently but not consistently in alloys containing substantial amounts of beta solid solution. These lines correspond in both angle and intensity to the four principal lines reported for the ternary compound, $MgLi_2Al$. Several alloys of composition approximating to $MgLi_2Al$ have been prepared and diffraction patterns obtained immediately after heat treatment in a purified helium atmosphere at 400°, 375° and 100°C. In all cases the alloys contain the compound AlLi with beta solid solution or with alpha + beta, but there is no trace of the four additional lines. The equilibrium compound, $MgLi_2Al$, does not, therefore, exist in the temperature range 100°–400°C. No evidence of the four additional lines is found in alloys containing 4–15% lithium and 12–30% aluminium after homogenizing treatment at temperatures of 400°, 375° and 100°C. They are only found in the region near the beta corner of the alpha-beta-AlLi and beta-AlLi areas and from specimens homogenized at 375°C. and aged at room temperature or 100°C. for a considerable period. Hence, although the lines cannot be reproduced consistently, even with specimens of the same alloy, it is believed that the four diffraction lines are due to a transitional structure.

For the 375° isothermal section the alpha-beta-AlLi field occupies a large part of the central section whereas the alpha-AlLi-$Mg_{17}Al_{12}$ field is extremely narrow. The solubility of aluminium in magnesium first decreases and then increases slightly until the alpha-$Mg_{17}Al_{12}$ boundary meets the corner of the ternary area for alpha solid solution and the two binary compounds. Above this point the solubility of aluminium again decreases. No additional phases appear in the 200° isothermal section. The alpha, beta, alpha-beta and alpha-$Mg_{17}Al_{12}$ fields, however, retract abruptly towards the binary surfaces, permitting a marked expansion of the four fields containing the compound AlLi. With a further decrease to 100°C., retraction of the alpha, beta, alpha-beta and alpha-$Mg_{17}Al_{12}$ areas continues much more slowly. As the beta solid solution is the most ductile phase, the portion of the equilibrium diagram of greatest interest, from the practical viewpoint of developing alloys combining good workability and strength, adjoins the alpha-beta/alpha-beta-AlLi phase boundary. It is shown that beta and alpha-beta alloys supersaturated with the compound AlLi can be obtained by quenching from a homogenizing temperature in the vicinity of 375°C., and that a massive precipitation of AlLi can be avoided by suitable ageing treatment.[176] The spectrographic character of the luminous trails generated by ultra-high-speed pellets of lithium–magnesium–aluminium has been investigated.[177,178] The properties of magnesium–lithium alloys containing aluminium and zinc and the effect of contamination of such alloys with sodium have been discussed.[35,49,63]

The system aluminium–zinc–lithium has been examined by thermal analysis and a study of the microstructure of the solid alloys. The phases in equilibrium with the alpha-solid solution of aluminium at room temperature are: beta-solid solution of zinc, phases of variable composition, gamma- and delta-, formed by a peritectic reaction, and epsilon-solid solution of the compound AlLi. The limits of alpha-solid solution have been determined at various temperatures.[179] The composition and temperature of the ternary eutectic are 4·31% of aluminium, 0·52% of lithium and the remainder zinc at 364·25°C.[74]

The spectral photoelectric sensitivities of germanium–lithium–silver compounds have been measured.[180]

A new phase has been observed in the lithium–germanium–aluminium system on introducing about 1% of lithium into an aluminium–germanium alloy containing about 65% of germanium; it consists of coarse angular particles in or alongside the primary germanium crystals, and on standing in air the light-grey colour of the new phase darkens and the surface becomes covered with deep cracks; a new phase in the aluminium–silicon–lithium alloys behaves similarly.[181] The following compounds have been prepared by Juza and Schulz[126] by heating together the binary phosphides or arsenides at the temperatures stated in brackets: Li_5GeP_3 (700°–1000°C.); Li_5TiP_3 (800°–900°C.); Li_3GaP_2 (450°–650°C. in the presence of excess lithium phosphide); Li_3GeAs_3 (700°–850°C.); Li_5TiAs_3 (600°–700°C.); Li_3GaAs_2 (450°–650°C.). The reaction is completed in two to three hours.

By thermal analysis, which shows three arrests on the cooling curve, a new ternary phase, $Li_xAl_ySi_z$ has been detected in the aluminium–silicon–lithium system; the new phase appears as light grey to light lilac crystals against a background of a solid solution of silicon in aluminium and of fine dark grey crystals of silicon. The new phase gradually becomes covered with a network of thin cracks.[182] Electrolysis of barium aluminate with cryolite and lithium halide yields no definite compound but an alloy of aluminium, barium and lithium.[183]

The effect of lithium in alloys[184,185] and the use of lithium alloys for purifying metals and alloys[186] have been described. The addition of lithium has little effect on the creep strength of magnesium–cerium alloys at 250°, 300° and 316°C.[187] The addition of lithium to silver–copper alloys nullifies the harmful effects produced by the presence of solid inclusions such as cuprous and cupric oxides.[188]

In making alloys of light and heavy metals, the light metal, such as lithium, is introduced in measured amount into a cavity formed in a relatively dense metal or alloy, the opening is closed and the whole heated until the interior unites with the exterior metal. The metal object thus obtained is added to the principal metal to be alloyed in the fusion bath.[189] A similar device employing a cartridge for below-surface treatment of molten metals is described. A metal container with a cavity filled with lithium is closed with a fusible plug of melting point above that of lithium and below that of the cartridge case. The weight of the cartridge and its charge exceeds the weight of the corresponding volume of molten bath metal into which the cartridge is lowered.[190] An improved tumbler stirring mechanism for the incorporation of additives into molten metal (particularly cast iron) is especially suitable for mixing highly volatile or explosive materials. Lithium or magnesium may be added by means of this device.[191]

An account of lithium and its alloys is given by Shamraiǐ.[192]

SECTION VI

LITHIUM HYDRIDE

By MARY R. TRUTER

At ordinary temperatures lithium hydride is an ionic solid compound of lithium cations and hydrogen anions. It is a very light, white salt which melts at 680°C. and is decomposed by water. In general, liquids that are normally used as solvents for investigating chemical reactions either do not dissolve lithium hydride or they are decomposed by it. Consequently, investigation of its chemistry is severely limited, and those reactions that have been explored are of necessity heterogeneous. This in turn means that it still has no important industrial uses.

Formation, Preparation and Production

It has long been known[1] that lithium hydride is formed by the direct action of molecular hydrogen on molten lithium. Other reactions by which the hydride is formed have been noted more recently. The reaction of atomic hydrogen with the solid metal at room temperature is instantaneous.[2] Lithium hydride is precipitated by the reaction[3] between lithium methyl and triphenyltin hydride in ethereal solution in a stream of nitrogen. The hydride is also formed[4] from lithium methyl by reaction with lithium aluminium hydride: again reaction occurs in ethereal solution and a white precipitate containing 88% of lithium hydride is formed; but this reaction is merely of interest as an illustration of a general method for preparing metallic hydrides, because the lithium aluminium hydride is itself prepared from lithium hydride.

The rate of reaction between lithium and hydrogen or deuterium has been studied by several workers.[5-7] The rate of formation of the deuteride is somewhat greater than that of the hydride.[5] In a recent study of the rate of reaction and the influence of promoters,[7] metallic lithium (0·25g.) in a nickel boat was placed in a 500 c.c. vessel and heated to 500°C. and 525°C. in vacuum. Hydrogen was admitted until the pressure reached 0·5 atm. and the rate of fall in pressure was measured manometrically. Reaction was fairly slow at both temperatures, e.g., at 500° the metal absorbed 118 times its own volume of gas in 30 min. At higher temperatures lithium sublimes at pressures less than atmospheric, and so the normal preparation of the hydride is carried out at increased pressures. In other experiments lithium metal, in hydrogen at 0·5 atm. pressure, was heated from room temperature at the rate of 2–3°C. per min. At first the pressure increased linearly because of thermal expansion, then the rate ceased to be linear because absorption of hydrogen had started (at temperature t_i). Eventually the rate of absorption became greater than the rate of thermal expansion (see Fig. 1) so that the pressure decreased as the temperature increased. Thus, the pressure passes through a maximum at a temperature t_c. Addition of small amounts of other metals, 'promoters', to the lithium generally results in a reduction of t_i and t_c, as shown in Table I.

It is interesting to note that t_c corresponds to the temperature of formation generally quoted in the literature, the early investigations[8] having shown that there was a small uptake of hydrogen at 300° followed by an induction period

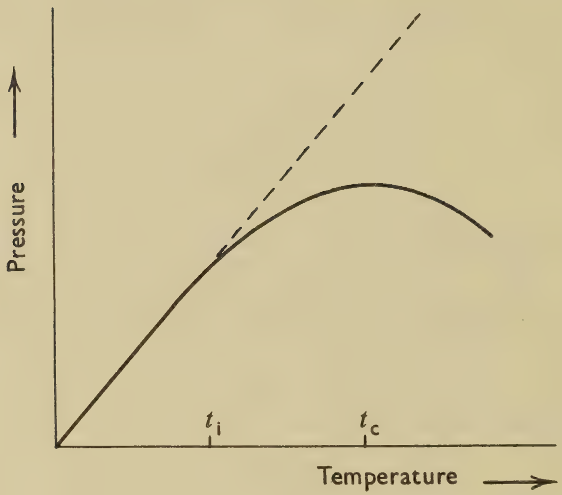

FIG. 1.

TABLE I. - EFFECT OF 'PROMOTERS' ON THE FORMATION OF LITHIUM HYDRIDE[7]

Promoter:	None	5·56% Mn	5·5% Ce	5% Ca	6·65% Ni	7·1% Ni + 4·8% Mn
t_i, °C.:	200	170, 170	160, 175	200, 200	250	150
t_c, °C.:	550	375, 400	490, 490	500, 500	450	450

in which no reaction took place, then a very vigorous reaction set in at 500–520° and was complete in 10 min. Soliman[7] showed that the absorption at temperatures below 500° was due to reaction and not to solution because no hydrogen was given off on cooling.

The earliest method for preparing lithium hydride is still the only practical one, and in 1950 details for the preparation of over a kilogram of very pure hydride were given.[9] The metal (890g.) was quickly placed in a reaction vessel which could be evacuated and was contained in a furnace. After the apparatus had been evacuated, hydrogen was admitted and allowed to flow slowly through at a positive pressure of about 0·25 atm. During an hour the furnace was heated to 500°C., at which temperature the reaction became perceptible. The temperature was raised to 650° and then kept approximately constant below 700° (the m.p. of the hydride is 680°). The lithium hydride formed is completely soluble in lithium. After about three hours, when no further absorption of hydrogen was detectable, the vessel was kept at 690° for 20–30 min. and then allowed to cool slowly, during two hours, to 300°, after which it was cooled more rapidly. The yield was 98·5% of the theoretical, and the product had a purity of 99·6%. Some preparations are white and some have a faint blue tint, but they are not distinguishable chemically. This method has been used by later workers, some of whom have suggested minor improvements in the apparatus.[10]

Commercial production of lithium hydride is also based on the reaction of hydrogen with molten lithium. Patents deal either with methods for producing the metal from its compounds[11-14] or with methods for increasing the rate of reaction (so that a lower temperature can be used) by increasing the surface area of the metal.[15-17]

To increase its surface area, the molten metal is mixed[15] with finely divided sodium hydride and 0·1–1·0% of a salt of a fatty acid or a hydrocarbon containing more than eight carbon atoms per molecule; the temperature required for the reaction is about 450°C. Alternatively, molten lithium, a metallic hydride and sand or clay are mixed and allowed to react, at about 385°C., with hydrogen containing 0·05–1% of an acetylenic hydrocarbon.[16] In another method the molten metal, dispersed in an inert hydrocarbon oil, is allowed to react at about 450°C. with hydrogen under a pressure of about 33 atmospheres.[17]

Physical Properties

Lithium hydride is the simplest of all known stable compounds and the second simplest diatomic molecule, consisting of two nuclei and four electrons. It is inevitable, therefore, that it should have been the subject of considerable calculation, many theoretical approaches having been tested by their ability to predict the physical properties of lithium hydride. The two extreme postulates for the bonding are (a) that there is an electron-pair bond and (b) that there is complete ionization into two helium-type ions Li^+ and H^- both in the solid and in the gas, the latter consisting of ion pairs. Some of the physical properties have been calculated although they have not yet been measured, e.g., the dipole moment, and attempts have been made to derive values[1,2] for unmeasurable properties, e.g., the normal potential for the hydride ion.

Melting Point, Density and Crystal Structure.

Lithium hydride is usually a white crystalline solid at room temperature; the hydride melts at 680°C.[3] and the deuteride at 686 ± 5°C.[4] Early workers[5] observed that the solid changed colour in daylight, becoming pink or brown. In ultra-violet light it becomes blue and the colour can be discharged by heating the solid; this behaviour is similar to that of the alkali halides and was one of the observations that led Moers[5] and Nernst[6] to postulate that the compound was a salt analogous to lithium fluoride. Moers's classical work[5] also showed that the crystals are isotropic, like those of the lithium halides, and that the solid can be electrolyzed to give hydrogen at the anode and metallic lithium at the cathode. The analogy with the halides of lithium was more apparent when the crystal structure was found[7] to be of the rock-salt type like the lithium halides.

From *X*-ray diffraction photographs the axis length, *a*, of the cubic unit cell has been determined. Values of *a* are shown in Table II together with the calculated density and molecular volume. The density, and hence the molecular volume, have also been determined pyknometrically. Here, the main difficulty arises from the necessity for absolutely anhydrous conditions. The results and comparable predicted values are also shown in Table II. It is interesting to note the contraction in the lattice when hydrogen is replaced by deuterium.

Zintl and Harder[13]	1931	*X*-Ray	4·084	0·77	10·32
Idem.[14]	1935	*X*-Ray LiH LiD	4·085 ± 0·001 4·065 ± 0·001	0·774	10·33 10·18
Tronstad and Wergeland[4]	1938	*X*-Ray LiH LiD	4·085 ± 0·001 4·063 ± 0·001	0·878 ± 0·002	–

The intensities of the *X*-ray reflexions have been measured by three independent groups of workers, from powder[13,16] and from single-crystal[17] specimens, and all three sets of results have been shown[18] to be in good agreement, so that there is no doubt about the accuracy of the experimental data. All these investigations have shown that the atoms or ions are arranged in a rock-salt (NaCl) lattice, so that the measured intensities of the reflexions should depend only upon the scattering powers (scattering factors[15]) of the atoms or ions, and these in turn depend upon the electron-density distributions. Thus it appears that measurement of the intensities might show whether the crystal contains the ions Li^+ and H^-, each with two electrons, or the atoms Li (with three electrons) and H (with one electron), the number of electrons being equal to the scattering factor at $\sin\theta = 0$. Further, the observed electron-density distribution could be compared with that calculated from various theoretical models. Attempts to deduce the charges on the ions have led to values ranging from[13] 1 to 0·25.[17] Recently it has been shown that the scattering factors for H and H^- are nearly the same,[18] and independently that the scattering factors from models with charges of unity or zero are nearly the same[19] at observable values of sin θ, so that the extrapolation to sin $\theta = 0$ is not likely to give a significant result. Theoretical treatments have also indicated quite different charges, 0·35 in[20] 1936 and nearly 1 (corresponding with an ionic structure with some overlap) in 1953.[19]

The coefficient of thermal expansion has not been measured, but has been calculated[21] to be $3{\cdot}9 \times 10^{-5}$ per degree for lithium hydride, $5{\cdot}7 \times 10^{-5}$ per degree for lithium deuteride and, for the still unknown lithium tritide, $6{\cdot}3 \times 10^{-5}$ per degree. From measurements[22] of the intensities of the lines on the *X*-ray powder diagram from 20°K. to room temperature, the Debye characteristic temperature[23] was calculated to be 851°K. for lithium hydride and 638°K. for lithium deuteride.

The refractive index of the crystals is $n_D = 1{\cdot}615$, corresponding to a molar refraction of 3·94 for lithium hydride.[12]

Lattice Energy and Specific Heat.

Values for the ionic lattice energy, U_0, calculated from the Born cycle and from spectroscopic data, have been compared with those predicted theoretically; unit-cell dimensions have also been predicted. The quantities required for the Born cycle and the assumptions made in the determination of the lattice energy from the absorption spectrum of the solid are shown below.

$$\begin{tikzcd}
Li^+H^-(s) \arrow[r, "U_0"] \arrow[dr, "h\nu"] & Li^+(g) + H^-(g) \arrow[d, "E-I"] \\
Li(s) + \tfrac{1}{2}H_2(g) \arrow[u, "-\Delta H_f"] & Li(g) + H(g) \arrow[l, "S + \tfrac{1}{2}D(H_2)"']
\end{tikzcd}$$

Thus, $U_0 = I - E + S + \tfrac{1}{2}D_{(H_2)} - \Delta H_f$, where I is the work of ionization for lithium, E is the electron affinity of hydrogen, S is the heat of sublimation of lithium, D is the dissociation energy of hydrogen and ΔH_f is the heat of formation of lithium hydride. It was assumed[35] that the absorption spectrum of the solid arises from an electron transfer within the lattice. There is a sharp maximum at 2517 ± 2A. in the absorption spectrum of lithium hydride[35,37] and at 2482 ± 5A. for lithium deuteride.[35] From these observations the values of the lattice energies in Table III were derived,[35] the value of E being taken as 16·4 kg.-cal. per g.-mol. In a critical evaluation of all the previous theoretical work on the solid, Lindqvist[26,27] points out that a completely ionic model is not as acceptable for the hydride as for the alkali halides because the hydride

TABLE III.- CALCULATED UNIT-CELL DIMENSIONS AND LATTICE ENERGIES OF LITHIUM HYDRIDE

Workers	Date	*a*, calc.	U_0(kg.-cal./g.-mol.)	
			Predicted	Born cycle
Kazarnovskii[1]	1928	–	234	234

Lindqvist[26]	1954	–	205	–

ion is more easily deformed. A summary of the results of calculation by wave or quantum mechanics and from experimental data is given in Table III.

The zero-point energy has been calculated in a number of ways; from the more rigorous London formula it is 1·12 kg.-cal. per g.-mol. for lithium hydride and 0·59 kg.-cal. per g.-mol. for lithium deuteride,[28] whereas for one approximation values of 5·49 and 4·30 kg.-cal. per g.-mol., respectively, are obtained,[28] and for another approximation 3·69 and 2·77 kg.-cal. per g.-mol. respectively.[4] Values deduced from spectroscopic data are 1·9797 and 1·4878 kg.-cal. per g.-mol. for lithium hydride and lithium deuteride, respectively.[4] Although the actual values depend upon the theory invoked, there is agreement that the zero-point energy for the deuteride is less than that for the hydride, in harmony with the suggestion[29] that the observed contraction in the lattice is due to the difference in zero-point energy. The calculated contraction,[29] however, is only half that observed.[14]

The molar specific heat of the solid calculated from Debye's formula[30] is in good agreement with that measured[31] over a range of temperatures from 74°K. to room temperature; the values are shown in Table IV.

TABLE IV. - THE MOLAR SPECIFIC HEAT OF LITHIUM HYDRIDE

Temperature, °K.	Specific heat:	
	Observed	Calculated
74·0	0·68	0·74
75·2	0·74	0·70
76·6	0·76	0·72
77·6	0·72	0·76

93·0	1·34	1·32
95·7	1·38	1·42
292·7	8·18	8·24

Heat of Formation and Heat of Hydrolysis.

The heat of formation of lithium hydride has been measured indirectly from the heats of hydrolysis of lithium and lithium hydride, and directly by measurement of the decomposition pressure: it has also been calculated from the absorption spectrum of the solid. The results of these measurements are in good agreement, as shown in Table V.

TABLE V. - HEAT OF HYDROLYSIS AND HEAT OF FORMATION OF LITHIUM HYDRIDE

Authors	Date	Method	ΔH_h kg.-cal./g.-mol.	ΔH_f kg.-cal./g.-mol.
Guntz[32]	1896	Calorimeter	-31·97	-21·61
Moers[5]	1920	Calorimeter	-31·62	-21·60 ± 0·25
Messer, Fasolino and Thalmayer[33]	1955	Calorimeter	-31·76 ± 0·10	-21·34 ± 0·15
Hurd and Moore[34]	1935	Vapour pressure	-	-22 ± 1
Kapustinskii, Shamovskii and Bayushkina[35]	1937	Absorption spectrum	-	-22·9(LiH) -23·6(LiD)

Calorimetric measurements of the heat of hydrolysis of the solid:-

$$LiH_{(s)} + aq. \rightarrow LiOH_{aq.} + H_{2(g)};\ \Delta H_h,$$

and of the heat of hydrolysis of metallic lithium, have been made by three independent workers.[5,32,33] By comparing the two results, the heat of formation, ΔH_f may be obtained:-

$$Li_{(s)} + \tfrac{1}{2}H_{2(g)} \rightarrow LiH_{(s)};\ \Delta H_f.$$

The most recent workers claimed greater accuracy on the grounds that they used lithium hydride of greater purity; their results[33] refer to infinite dilution at 25°C.

Other values for the heat of formation have been obtained by measurement, at various temperatures, of the vapour pressure, assumed to be entirely due to the hydrogen. The heat of the decomposition reaction ($-\Delta H_f$) was calculated in the usual way from a plot of log (pressure of H_2) against the reciprocal of the absolute temperature. Technically the measurements are very difficult, all authors[4,10,33,36] having failed to obtain reproducible results; the figures quoted in Table VI are either those the authors[10] regarded as fairly reliable or the result[33] of a single successful run.

TABLE VI. - DECOMPOSITION PRESSURE OF LITHIUM HYDRIDE

Authors	Date	Temp. °C.	Pressure, mm.
Hüttig and Krajewski[10]	1924	23	0·023
		150	0·05
		170	0·11
		190	0·34
Hurd and Moore[34]	1935	509	0·10
		597	1·85
		598·5	1·75
		649	7·30
		653	7·80
Guntz[32]	1896	680	26·8

Calculation of the heat of formation from the absorption spectrum of the solid is based on the assumption, already illustrated (see page 135) that the following equation may be used to evaluate ΔH_f:-

$$h\nu = -\Delta H_f + S + \tfrac{1}{2}D.$$

From the observations[35] (λ = 2517A. for LiH and λ = 2482A. for LiD) and the values 51·83 and 52·72 for half the dissociation energy of hydrogen and deuterium, respectively, the values for the heat of formation of the hydride and deuteride given in Table V were derived. From the same data the heat for the reaction:-

$$LiH + D \rightarrow LiD + H,$$

was calculated to be 1·6 kg.-cal. per g.-mol.; the formation of the deuteride is exothermic, as is to be expected from its more rapid formation[4] than the hydride from the metal.

Irradiation[37] of solid lithium hydride with light of wave-length 2537A. liberates hydrogen in a 5% quantum yield; it is thought[37] that only interstitial hydrogen is thus liberated from the lattice.

Electrical and Magnetic Properties.

Electrolysis provided much of the original evidence for the conclusion that the solid is ionic. Electrolysis of the solid, *in vacuo*, using direct current, led to an increase in pressure[5] and the appearance of metallic lithium at the cathode. Later[38] it was proved that the gas was hydrogen and the yield is 99·5% of that calculated from Faraday's law (assuming an H^- ion), but the yield of metallic lithium is less than the calculated value because the metal is soluble in the hydride. The minimum potential required to release hydrogen is 0·1V.[39] More recently[40] it has been found that the optimum yield of hydrogen at the anode (>80% of the theoretical) can be obtained by passing a current through the solid at a temperature just below its melting point (680° C.) for 2·5 min.; if the temperature is raised or the duration of electrolysis increased the yield is reduced.

The solid is diamagnetic, having a molar magnetic susceptibility, measured[41] on a Gouy balance, of $-4{\cdot}60 \times 10^{-6}$ c.g.s. units (within 2%) at both 300°K. and 78°K. This experimental value is less than one half of the lowest of the various predicted values and the discrepancy is attributed[41] to temperature-independent paramagnetism. The most recent calculation,[42] based on the sum of the values for helium-type ions, is $-11{\cdot}6 \times 10^{-6}$ c.g.s. units.

An interesting suggestion was made[43] in 1935 that the ratio of the nuclear magnetic susceptibility to the diamagnetic susceptibility would be 0·12 at 2°K. and 0·06 at 4°K., so that at very low temperatures it might be possible to measure the nuclear susceptibility.

A number of physical properties have been calculated but not observed directly. For example, from the lattice energy the compressibility has been calculated[24] ($2{\cdot}36 \times 10^{-12}$). The repulsion exponent has also been calculated; the value,[24] 4·1, is in agreement with the value 3·9, derived[44] from spectroscopic data for the gas.[45] The dipole moment of the gaseous molecule has been calculated[46] as 4·05D., using an empirical rule[47] based on ion-pair molecules, compared with 3·5D. deduced[48] from quantum-mechanical considerations. For the gas, the entropy calculated[49] from spectroscopic data[50] is 38·77 entropy units at 298·1°K. For the solid the entropy derived[51] from specific-heat data[31] is 5·9 ± 0·5 entropy units at 298·1°K.

Absorption and Emission Spectra; Dissociation Energy of the Gas.

A great deal of spectroscopic work has been carried out on gaseous lithium hydride and lithium deuteride. The emission spectrum was obtained from a lithium arc[52] in an atmosphere of hydrogen at reduced pressure. Later[45] the emission spectrum (λ 3200–5000A.) was observed by the same technique, and the absorption spectra (λ 3000–4500A.) of mixtures of lithium and hydrogen vapours at various temperatures (600°–900° C.) and pressures (50–160cm.) were also observed; full details are given in the paper.[45] In appearance the spectra, due to $^1\Sigma \rightarrow {}^1\Sigma$ transitions, are like those of molecular hydrogen and consist of many lines forming bands which show P and R branches, the latter being degraded towards the red. It is possible to distinguish between the spectra of ^{7}LiH and ^{6}LiH and those of the corresponding deuterides. Full details of the frequencies and assignments for ^{7}LiD and ^{7}LiH have been given[53,54] (see also page 284).

There are four combinations of the isotopes, ^{6}Li, ^{7}Li, H and D, and shifts in the positions of the spectral lines have aroused considerable interest. Comparison[55,56] of ^{6}LiH and ^{7}LiH showed that the relative positions of the lines were approximately as calculated, but that the relative intensities did not correspond to the ratio of natural isotopic abundance, ^{6}Li:^{7}Li = 1:13; in fact, when the mixture of hydrogen and lithium vapours was first heated the relative intensities of the spectral lines corresponded to a ratio ^{6}LiH:^{7}LiH of 1:2, and on prolonged heating this changed to 1:8.[55] Thus, apparently ^{6}Li forms a hydride more rapidly than does ^{7}Li. Comparison[57] of ^{7}LiH and ^{7}LiD shows an anomaly in that the empirical ρ values of the bands, expected to be in the ratios of the reduced masses, are sometimes larger and sometimes smaller than expected. Correction for anharmonicity (interaction between rotation and vibration) makes the anomalies smaller but does not remove them altogether. It seems[57] probable that they arise from an unusual potential-energy curve for the excited state. Part of this curve was calculated from the observations.[57] Later,[58] another part of the curve was calculated by Klein's method[59] using Nakamura's postulate[45] that the dissociation of the excited state is into excited lithium atoms, Li(^{2}P), and normal hydrogen atoms. The two parts of the curve joined satisfactorily. Another version of this potential-energy curve, based upon a simple electrostatic calculation,[73] is in good agreement.

A summary of the results of spectroscopic investigation is given in Table VII. Further discussion may be found in a number of papers;[60] see also page 284.

TABLE VII.- RESULTS OF SPECTROSCOPIC MEASUREMENTS ON LITHIUM HYDRIDE

Authors	Date	Interatomic distances, A.				Dissociation energy, electron volts per mol.		Moment of inertia, 10^{40} g. sq.cm.

Force constant for LiH, 6·5 × 10^5 dynes/cm.
Fundamental frequency, 1407 cm.$^{-1}$

For the gaseous molecule a number of theoretical calculations by different methods have led to the conclusion that ionic terms are important, and while, for a first approximation, the 1*s* electrons of lithium are assumed not to take part in bonding, more sophisticated treatments have shown that inclusion of these electrons makes a large difference to the calculated dissociation energy, *D*. Comparison of this with the observed value (2·5 e.V., see Table VII) is usually taken as a criterion for the correctness of the theory and the validity of the simplifying assumptions. At present, however, the best agreement is not given by the most rigorous treatments.

The earliest calculations[62,63] were based on the assumption that the molecule was entirely covalent and that the 1*s* electrons of lithium took no part in bonding. By the Heitler–London or electron-pair method[64] the following quantities were calculated:[63] interatomic separation, 1·44A.; *D*, 2·30 e.V.; and fundamental frequency, 1400 cm.$^{-1}$ Subsequent recalculation,[59] including a correction to one of the integrals, gave 1·53A., 1·30 e.V. and 1370 cm.$^{-1}$, respectively, results which indicated[65] that the assumption was not valid and that some ionic terms were required. Another early calculation (1934), based on the same assumptions and also on the assumption that the interatomic separation is 1·60A., gave D = 2·30 e.V. by a treatment exactly analogous to that for hydrogen by Hylleras.[65] Similarly in 1936 the application of a treatment[66] analogous to that of James and Coolidge[68] for hydrogen gave D = 1·89 e.V. At the opposite extreme, the assumption of complete ionization with each ion polarized in the field of the other gave,[46] by an empirical relationship,

D = 2·4 e.V. A simplification[67] of the molecular orbital treatment gave D = 1·855 e.V., and this corresponded to a model in which 66% of the electronic charge cloud of the binding electrons was situated on the hydrogen, 11% on the lithium and the remainder in overlap. The percentage ionic character calculated from the electronegativity difference (1·1) by an empirical formula[69] is 21·8. The most complete treatment[70] was carried out by the Hartree-Fock method. Four sets of calculations were made, viz. (a) for two electrons by the electron-pair method without ionic terms; (b), as for (a) but including ionic terms; (c) for two electrons by the molecular orbital method (linear combination of atomic orbitals); and (d) for four electrons by the molecular orbital method. The values of D were (a) 2·64 e.V., (b) 3·68 e.V., (c) 3·57 e.V. and (d) 2·0 e.V., at the observed interatomic distance. The equilibrium interatomic distances and fundamental frequencies were also calculated[71] by using the minimum-energy criterion, and as the variation from the experimental value was not more than 0·2A. it was concluded that the use of experimental interatomic distances would be justifiable in future calculations.[71] It is curious that the most rigorous treatment (*i.e.*, (d)) did not give the best value for the dissociation energy. The ratio of 2*p* to 2*s* in the hybridization was given as 0·41 by the most rigorous treatment and as less by the various approximations.[72] Quantum-mechanical calculation[74] indicated that LiH^+ would be unstable.

Chemical Properties

Lithium hydride reacts vigorously with water, giving lithium hydroxide and hydrogen. In many reactions lumps of lithium hydride are surprisingly inert; for efficient reaction it must first be powdered, in an atmosphere of dry nitrogen. Its main reactions are of the replacement type, leading to the formation of hydrides of other elements and of double hydrides. It is a particularly useful reagent for replacing halogens by hydrogen.

Treatment[1] of lithium hydride with benzoyl chloride dissolved in a high-boiling hydrocarbon, at about 200°C. for 4 hr., leads to the formation of benzyl benzoate, which may be distilled off under reduced pressure, leaving lithium benzoate in the residue.

Alkyl and alkenyl silanes can be prepared[2] from the corresponding chlorides, e.g., $RSiCl_3$ and R_2SiCl_2, by treating them with lithium hydride. The reaction is carried out in *iso*amyl ether, in which lithium hydride is insoluble. Unsaturated hydrocarbon radicals are not normally hydrogenated, so that propenyl trichlorosilicon can be converted into the corresponding unsaturated silane; the yield is about 40%.

A similar reaction is observed[3] with alkyl aluminium halides and lithium hydride. For example, treatment of a warm ethereal solution of diethyl aluminium chloride, Et_2AlCl, with a suspension of lithium hydride in ether gives diethyl aluminium hydride and lithium chloride.

Ethoxides of aluminium and boron give either the hydrides of these elements or, in the presence of excess lithium hydride, double hydrides.[4] The reaction between an excess of lithium hydride and an ethereal solution of aluminium ethoxide proceeds by three stages:-

$$\mathrm{LiH + Al(OEt)_3 \rightarrow Li[HAl(OEt)_3](+ LiH) \rightarrow Li[H_2Al(OEt)_2] + LiOEt(+ 2LiH) \rightarrow LiAlH_4 + 2LiOEt}$$

All the products containing aluminium are colourless crystalline compounds which are soluble in ether and react with water to liberate hydrogen.

Lithium aluminium hydride[5] can also be prepared by the action of lithium hydride (4g.) on aluminium chloride (2·7g.). The solids are mixed in an atmosphere of dry nitrogen and after the vessel has been evacuated, diethyl ether (15ml.) is distilled into the mixture at about −193°C. When the mixture is allowed to warm up, a vigorous reaction sets in, and this must be damped down by additions of liquid nitrogen. The reaction is completed in about five minutes. After the insoluble lithium chloride has been filtered off, the filtrate is evaporated to dryness under reduced pressure; the residue (2g.) is lithium aluminium hydride.

The disadvantage of this simple reaction is that it cannot be easily controlled. First, there is an induction period that may vary from a few minutes to several hours. Then, when the reaction does start, it proceeds with uncontrollable vigour and is complete within a few minutes. The reaction of gallium chloride with an excess of lithium hydride, on the other hand, proceeds smoothly to give lithium gallium hydride.

The best method of preparing lithium aluminium hydride involves the use of a small amount of this material as catalyst or 'promoter'. Solid lithium hydride (3mol.) is added to an ethereal solution of lithium aluminium hydride (0·08mol. in 30ml.). After the mixture has been well stirred, it is diluted with ether (200ml.) and a solution of aluminium chloride (0·5mol.) in ether (300ml.) is added at such a rate as to keep the reaction mixture boiling gently. The insoluble lithium chloride and the excess of lithium hydride are filtered off. The product obtained after removing the ether from the filtrate has a purity of about 95%.

If the amount of lithium hydride used corresponds to that in the equation:-

$$\mathrm{3LiH + AlCl_3 \rightarrow 3LiCl + AlH_3},$$

or if aluminium chloride is added to a solution of lithium aluminium hydride, after the lithium chloride has been filtered off, evaporation of the ethereal solution gives a white solid in which the ratio of aluminium to hydrogen is 1:3, but the compound also contains ether which cannot be removed.

Lithium aluminium hydride decomposes at 125°C. giving aluminium, hydrogen and lithium hydride. It reacts vigorously with compounds containing hydroxyl groups, e.g., acids, alcohols and water, liberating hydrogen. With an excess of water the products are hydrogen, lithium hydroxide and aluminium hydroxide. It is a useful reagent for the reduction of ketones and esters to the corresponding alcohols. It reacts with halides and alkyl derivatives to give hydrides, e.g.:-

$$Me_2Zn + LiAlH_4 \rightarrow ZnH_2 + LiAlMe_2H_2$$
$$SiCl_4 + LiAlH_4 \rightarrow SiH_4 + LiCl + AlCl_3$$
$$2Si_2Cl_6 + 3LiAlH_4 \rightarrow 2Si_2H_6 + 3LiCl + 3AlCl_3$$

With boron trichloride it gives diborane:-

$$3LiAlH_4 + 4BCl_3 \rightarrow 3LiCl + 3AlCl_3 + 2B_2H_6$$

Lithium aluminium hydride (0•277g.) dissolved in ether (5 ml.) is cooled in liquid nitrogen, and boron trichloride (1•279g.) is distilled into the vessel. A vigorous reaction takes place, presumably the formation of the complex between ether and boron trichloride, and when the mixture is allowed to warm up to room temperature, diborane is evolved in 99•4% yield. The action of diborane itself on lithium aluminium hydride leads to the formation of lithium borohydride and aluminium borohydride:-

$$LiAlH_4 + 2B_2H_6 \rightarrow LiBH_4 + Al(BH_4)_3$$

The simplest preparation is to pass gaseous diborane over lithium aluminium hydride at about 80°C. Aluminium borohydride is volatile and may be condensed in a cold trap while the lithium borohydride remains behind as the residue.

Diborane is also produced[6] by the action of lithium hydride on the ether complex of boron trifluoride:-

$$8BF_3,OEt_2 + 6LiH \rightarrow B_2H_6 + 6LiBF_4 + 8Et_2O$$

The boron trifluoride–ether complex is added to an ethereal suspension of finely powdered lithium hydride. The reaction starts at room temperature, and being exothermic, raises the temperature of the mixture to the boiling point of the ethereal solution. When the reaction has subsided, the mixture is refluxed for several hours, the volatile diborane being collected in a cold trap. Subsequently, the contents of the cold trap are purified by fractionation. This process is one of the most efficient for the preparation of diborane (80–95% yield) and has been patented.[7]

If this same reaction is carried out in the presence of lithium borohydride the course of the reaction is completely changed. Diborane is not evolved unless there is an excess of boron trifluoride present, and the products are lithium fluoride and lithium borohydride. It has been shown that the reaction proceeds in two stages. The first is the exothermic reaction to produce lithium borohydride:-

$$4LiH + BF_3 \rightarrow LiBH_4 + 3LiF;$$

then, in the presence of more boron trifluoride, endothermal decomposition sets in giving lithium fluoride and diborane:-

$$3LiBH_4 + BF_3 \rightarrow 2B_2H_6 + 3LiF.$$

The reaction with boron trichloride, on the other hand, gives lithium borohydride even in the absence of lithium borohydride to act as promoter. Similarly, boron trifluoride in the presence of ether and tetrahydrofuran will give lithium borohydride in the absence of a promoter. It has been suggested that the role of the promoter is to prevent contamination of the surface of the lithium hydride by insoluble complexes.

Direct reaction[8] between boron trifluoride and lithium hydride in the absence of ether does not lead to the production of diborane; the course of this reaction has not yet been elucidated.

If lithium hydride is treated with an ethereal solution of diborane, lithium borohydride is formed:-

$$2LiH + B_2H_6 \rightarrow 2LiBH_4$$

From the reaction of lithium hydride with methyl borate two intermediates, lithium boromethoxyhydride, $LiBH_2(OMe)_2$, and lithium boromethoxide, $LiB(OMe)_4$, have been isolated, in addition to the main end-product, lithium borohydride. It is believed that the primary reaction product is the unstable addition compound $LiBH(OMe)_3$.

It is stated[9] that, at 500°C. under reduced pressure, lithium hydride will reduce the chlorides of sodium, potassium, rubidium and caesium to give the free alkali metal and hydrogen. At the same temperature metallic lithium will react to form lithium chloride and the alkali metal, but the authors[9] considered that dissociation of the lithium hydride was not the primary reaction because the pressure of hydrogen (16–26mm.) was greater than the equilibrium pressure of hydrogen (0·07 mm.) over lithium hydride at 500°C. No hydrogen chloride was evolved in the reaction. The same workers[9] carried out reactions between lithium hydride and the oxides of Group IVA and Group VA metals at 500°C.; they report difficulty in analyzing the products of the reactions but find that while thorium dioxide is not attacked, zirconium and silicon dioxides are reduced to the elements and that germanium and titanium dioxides and niobium pentoxide are reduced to lower oxides.

Two extensive review articles have been published on hydrides in general, one[10] written in 1926 and the other in 1953,[11] and in 1954 a review on lithium hydride only.[12]

Uses

Lithium hydride has no large-scale uses. The following ideas, taken from the patent literature, show the directions of potential development.

Refs. p. 145

Lithium hydride may be used[1] as a reducing agent for refractory oxides, with which it is mixed and heated, *in vacuo*, at 800–900° C. Elements that have been prepared in this way are chromium, beryllium, boron, zirconium, uranium and tantalum. The sulphur content of iron can be reduced to 0·009% by the addition of lithium hydride[2,3] at the slag-metal interface.

As a reducing agent it is a possible rocket fuel,[4] the oxidizing agents being the oxides, fluorides or oxyfluorides of nitrogen.

It has been used as a catalyst in a number of polymerizations, for example, in the polymerization of butadiene to synthetic rubber,[5] and in the production of analogues of 'Terylene'. Normal production of 'Terylene' is by ester interchange between methyl terephthalate and ethylene glycol; these are heated under reduced pressure and the methanol is pumped off. Various catalysts, including lithium hydride[6,7] have been suggested for reactions between alkyl terephthalates and polyethylene glycols.

Electrolysis[8] of an anhydrous diethyl ether solution of 2–3M. aluminium chloride and 0·5–1·0M. lithium hydride at 5 amp./sq. in. gives a ductile deposit of aluminium.

Perhaps the most important use is in the production of lithium aluminium hydride[9] which is finding increasing application in the field of organic chemistry.

Lithium hydride has limited use as a convenient method of transporting hydrogen[10] because it liberates one-quarter of its weight of this gas on the addition of water.

SECTION VII

LITHIUM OXIDE

By R.E. OLIVER

PREPARATION AND PRODUCTION

Lithium oxide may be prepared by direct combination; despite the extreme readiness with which the elements combine, it is difficult to carry out the reaction under controlled conditions, owing to the protective film of oxide formed on the surface of the metal. Direct combination is better undertaken in a liquid-ammonia system.[1] Lithium metal (1•5 g.) is dissolved in liquid ammonia (30 ml.). A blue solution results. Oxygen is passed in until the solution is colourless, and the ammonia is then removed by evaporation. The product contains approximately 23% of lithium peroxide and 77% of lithium oxide. Heating to 300°C. decomposes the peroxide present, leaving a pure lithium oxide sample.

Lithium hydroxide may be decomposed by heating in vacuum[2] according to the equation:

$$2\ LiOH \rightarrow Li_2O + H_2O \uparrow$$

The reaction is carried out in platinum, and at 1000°C. is complete after several hours.

Lithium carbonate may be decomposed in a similar manner:[3,4]

$$Li_2CO_3 \rightarrow Li_2O + CO_2 \uparrow$$

Again the reaction is carried out in platinum, with the decomposition temperature in the range 700–1000°C.

Two further laboratory preparations are described below.

(i) To a saturated solution of lithium hydroxide in ethyl alcohol at 95°C. is added the theoretical quantity of perhydrol.[1] Lithium peroxide is precipitated, which after washing with alcohol is decomposed to lithium oxide by heating to 300°C. Very pure samples of the oxide may be made in this way.

(ii) Lithium metal (2 g.) is dissolved in ethyl alcohol (250 ml.) under an atmosphere of helium.[5] Lithium ethoxide is precipitated; this is filtered and washed with alcohol. It is then slurried with a further 250 ml. of alcohol, and 25 ml. of 30% hydrogen peroxide are added. After stirring for several hours, LiO_2H,H_2O separates in approximately 56% yield; this compound is dehydrated at 20 mm. pressure over phosphorus pentoxide to give lithium peroxide, which is then decomposed to the oxide by heat.

PHYSICAL PROPERTIES

Structure.

The crystal structure of lithium oxide is cubic and of the anti-fluorite type, with oxygen replacing calcium and lithium replacing fluorine in the fluorite lattice.[3,6,7] The lattice parameter is 4•619 A.[7] Lithium atoms lie at the centres of perfect oxygen tetrahedra.[3] The interatomic distances[3] are:

Li–O	2•00 A.
Li–Li	2•32 A.
O–O	3•27 A.

The molecular volume of lithium oxide is 8·3 c.c.[8]

Density.

The density of lithium oxide is 2·02 g./c.c.[6]

Melting Point.

There are two recently published values, which however are not in agreement:

1427 ± 15°C.[9]
1570°C.[14]

Volatility and Stability.

Early work on the volatility of lithium oxide[11] is very conflicting and in many cases is vitiated by the presence of water. The apparent volatility in the presence of traces of water is much higher, owing to the volatilization of very stable lithium hydroxide molecules.

Lithium oxide samples have been heated to 1000°C. in magnesia boats, both under vacuum and in the presence of oxygen.[12] Losses in weight were proportional to the initial quantity of lithium oxide, indicating that they were a function only of the impurities present. The volatilization of lithium oxide at this temperature is insignificant. The vapour pressures of lithium oxide and lithium in equilibrium at 1000°K. are:

Li_2O 1×10^{-4} atm.
Li 1×10^{-12} atm.[13]

This is a point of difference between lithium and the other alkalis,[13] for which the magnitude of these values is reversed. There is no indication of appreciable volatility even at 1570°C.[10]

It has been shown by calculation that the vaporization of lithium oxide as its gaseous elements alone is unlikely, since the experimental vapour pressures are higher than the calculated values.[9] It is thought more likely that the vapour also contains molecules of lithium oxide, and under oxidizing conditions molecules of LiO.

Conductivity and Electrode Potential.

The conductivity of molten lithium oxide has been determined.[14] Fused magnesia crucibles were prepared by drilling large synthetic crystals. The crucible was placed in a carbon crucible and heated by induction under an atmosphere of argon. The electrodes were made from 40% rhodium/platinum alloy which was found to be almost completely resistant to the melt. Up to 20% of the lithium oxide present attacked the crucible, but the conductivity was found to be independent of the magnesium oxide concentration. The equivalent conductivity at 1570°C. was 108 $\text{ohm}^{-1}\text{cm.}^{-2}$ ± 20%.

The electrolyte behaviour of some fused silicate systems including Li_2SiO_3 has been studied.[15-18] Within the experimental error the conduction has been shown to be wholly ionic. The system was studied under vacuum in a molybdenum cell at temperatures up to 1800°C.; a carbon anode was used. Measurement of the oxygen liberated showed that Faraday's Laws were obeyed. Apparent deviations were due to secondary reactions at the electrodes. The conductivity increases with increase in concentration of lithium oxide.

Lithium oxide is completely ionized in fused cryolite and fused lithium metaborate.[19]

The electrode potential of lithium oxide in molten lead silicate has been studied.[20] In a cell of the type

$$- \text{Pt} : O_2 \mid PbSiO_3 + Li_2O \mid PbSiO_3 \mid O_2 : \text{Pt} +$$

the negative potential increased with increasing concentration of lithium oxide, and also in the order:

$$K_2O > Na_2O > Li_2O,$$

indicating that the electrodes respond to the oxygen-ion activity as a function of the concentration and basicity of the oxides dissolved in the melt. In the lithium oxide–lead silicate system an almost linear relationship was found between concentration of lithium oxide and electrode potential.

Concentration	Electrode Potential
0·4 mole Li_2O / 1 mole $PbSiO_3$	–400 mV.
0·1 mole Li_2O / 1 mole $PbSiO_3$	–190 mV.

Heat Content.

Values are listed in Table I.

TABLE I.- MOLAL HEAT CONTENT OF LITHIUM OXIDE ABOVE 298·16°K.[21]

Temp. °K.	$H_T - H_{298 \cdot 16}$ (g.-cal.)
427·7	1836
515·0	3303
625·2	5208
690·6	6403
823·8	8925
954·4	11529
1045·1	13376

Systems Containing Lithium Oxide.

These are considered under the section dealing with the application of lithium oxide in the glass industry.

CHEMICAL PROPERTIES

Lithium oxide is a powerful base, analogous in almost all respects to sodium and potassium oxides. It reacts readily with water to give the hydroxide and with numerous acidic substances to give the corresponding lithium salts. Owing to the lengthy nature of its preparation, it is seldom used as such, the hydroxide and carbonate usually providing a convenient alternative for wet and dry reactions.

Several high-temperature reactions of lithium oxide have been studied in recent years.

A phase diagram constructed from thermal analysis curves[22] has shown the existence of further lithium borates in addition to the well-known monoborate $LiBO_2$ and diborate $Li_4B_2O_7$. New phases (decomposition temperatures in parentheses) corresponding to $3Li_2O,B_2O_3$ (695°C.), $3Li_2O,2B_2O_3$ (685°C.) and $Li_2O,3B_2O_3$ (835°C.) have been identified.

The reaction between silica and lithium oxide[23] gives first the metasilicate, Li_2SiO_3. The melting point of the metasilicate is 1201°C., but it may be formed by sintering at a substantially lower temperature (800–900°C.). At higher temperatures the metasilicate will react with further lithium oxide to give an orthosilicate, Li_4SiO_4 (m.p. 1250°C.). As the temperature is further raised, the addition of lithium oxide gives Li_6SiO_5 and then Li_8SiO_6. The rate of reaction of silica with the alkali-metal oxides[24,25] is in the order

$$K_2O > Na_2O > Li_2O$$

and practical relationships have been derived based on the silica particle-size. A sharp increase in the rate occurs at 870°C., caused by the rapid disruption of SiO_4 tetrahedra in the inversion of quartz to tridymite. Fused Li_2SiO_3 has been electrolyzed.[26] Lithium is produced at the cathode, but reacts with the melt to liberate silicon. This secondary reaction results in the formation of a series of lithium–silicon alloys and Li_6Si_2.

In the reaction between lithium oxide and alumina[23] two products are formed according to the equations:

$$Li_2O + Al_2O_3 \rightarrow 2LiAlO_2;$$
$$3Li_2O + Al_2O_3 \rightarrow 2Li_3AlO_3.$$

Finely divided zirconia reacts slowly with lithium oxide to give $LiZrO_3$. Conversion is complete after 3 hr. at 1350°C.[27]

In a similar manner lithium oxide will react with germanium dioxide to give Li_2GeO_3 (m.p. 1237 ± 3°C.) which with further lithium oxide gives Li_4GeO_4 (m.p. 1295 ± 3°C.).[28]

Lithium oxide reacts with vanadium pentoxide to form the three normal vanadates[29] $LiVO_3$ (m.p. 618°C.), $Li_4V_2O_7$ and Li_3VO_4. When lithium metavanadate reacts with further quantities of V_2O_5 compounds known as vanadyl vanadates[29,30] are formed. Oxygen is evolved and this is thought to be due to the reduction of V_2O_5 to V_2O_4, giving compounds of the type:

$$5Li_2O, V_2O_4, 11\ V_2O_5;$$
$$9Li_2O, V_2O_4, 23\ V_2O_5;$$
$$3Li_2O, V_2O_4, 11\ V_2O_5.$$

These compounds have certain applications as semi-conductors.

APPLICATIONS

Lithium oxide is very widely used as a constituent of glasses. Several attempts have been made to classify the components of glasses and to forecast the effect of change of concentration, substitution, and addition of constituents. Such classifications include a scale of decreasing acidity,[31] the effect of various oxides on surface tension,[32] and a measure of the strength of bonding in the system, given by the expression z/a^2, where z is the valence of a given cation and a its distance from adjacent oxygen ions.[33]

A summary of the behaviour of lithium oxide with respect to the change in properties of some of the systems containing it is given below.

Silicate and Borosilicate Systems.

In the system Li_2O–SiO_2 a glass is formed on cooling melts containing up to 20% Li_2O.[34,35] If larger quantities of Li_2O are present[36] devitrification sets in rapidly at 500–600°C. and is complete at room temperature. Glasses containing up to 50·09% Li_2O have been studied and the volatilization of Li_2O from the melt observed. A system containing 38·22% Li_2O had a vapour pressure of 0·50 mm. at 1300°C. and lost 41 mg. Li_2O per sq. cm. of melt surface in 20 hr. An equilibrium diagram of the system shows the existence of three compounds, $2Li_2O, SiO_2$, Li_2O, SiO_2 and $Li_2O, 2SiO_2$.[37] Melts in the system Li_2O–B_2O_3–SiO_2 devitrify on cooling. To obtain a stable glass it is necessary to add alumina.[34] Such glasses have application as solder glasses.[38]

Al_2O_3–B_2O_3–SiO_2 glasses containing approximately 14% Li_2O have been made with electrical resistivities in the range $10^9 - 10^{10}$ ohms per cm. cube. These values compare with 10^{13} for soda-lime glasses at room temperature. Dielectric constants have also been measured.[34]

The effect of substituting Li_2O for Na_2O and K_2O in the systems Na_2O–SiO_2 and K_2O–SiO_2 has been studied.[39] A maximum density was found when the ratio was 1:1. Improved chemical resistance was observed.

Several compounds in the Li_2O–K_2O–SiO_2 system were identified:

$$Li_2O, K_2O, 4SiO_2,\ \text{m.p. } 870°\text{C.};$$
$$Li_2O, 2K_2O, 6SiO_2,\ \text{m.p. } 815°\text{C.};$$
$$2Li_2O, 5K_2O, 7SiO_2,\ \text{m.p. } 900°\text{C.};$$

Refs. p. 156

$Li_2O,5K_2O,7SiO_2$, m.p. 880°C.;
$Li_2O,5K_2O,4SiO_2$, m.p. 830°C.

The partial replacement of Na_2O by Li_2O in the system $Na_2O-CaO-SiO_2$ has many advantages.[40] The glasses formed smelt and fire well and have a lower softening point. Additions of small quantities of lithium oxide enable glasses of low expansion coefficient in this system to be smelted. The lithium may be added as lepidolite, which therefore includes the addition of alumina, resulting in glasses of improved chemical resistance.

The addition of small quantities of lithium oxide to the crystallization of cristobalite at 1400°C. resulted in the formation of tridymite.[41]

The effect of replacing sodium or potassium oxide by lithium oxide in iron-containing glasses[42] is to give a higher proportion of ferrous iron in the structure, with a resulting diminution of ferrosoferric oxide (Fe_3O_4), ferric oxide and colourless iron (structure building units analogous to SiO_4 tetrahedra).[43] In a $K_2O-Na_2O-PbO-SiO_2$ glass containing iron, ferric oxide is very stable. The effect of introducing lithium oxide is to form some ferrosoferric oxide, indicating that the greater mobility and field strength of lithium over sodium and potassium has reduced some of the iron to the ferrous state.

In the glass system $Na_2O-(MgO-CaO)-SiO_2$[44] the substitution of Li_2O for Na_2O gradually decreases the liquidus temperature in a system containing 14% Li_2O, 12% CaO and 74% SiO_2. In a 18% Li_2O, 10% CaO and 72% SiO_2 system it had little effect. The addition of lithium oxide reduced the resistance to attack by water and dilute sulphuric acid. Sodium and potassium oxides gave the highest resistance to attack, while any pair of alkalis was an improvement upon the alkalis individually. Addition of lithium oxide greatly decreased the deformation temperature in both series.

The Winkelmann and Schott factors for effect upon thermal expansion[45,46] are Na_2O 10, and K_2O 8·5. Most recent work indicates that lithium oxide is as effective as sodium oxide in promoting high expansibility.

In the system $Na_2O-(MgO-CaO)-SiO_2$ addition of lithium oxide[44] caused large increases in the coefficient of expansion.

In the system $Li_2O-CaO-SiO_2$, weight for weight substitution of sodium oxide for lithium oxide resulted in a decrease of coefficient of expansion,[47] while mole for mole substitution resulted in an increase. In each case the softening point was raised.

In the systems $Na_2O-(MgO-CaO)-SiO_2$[44] and $Na_2O-CaO-SiO_2$[43] the addition of lithium oxide in all cases reduced the viscosity. More general investigation[48,49] has shown that the viscosity of silicate melts depends upon the following factors:

(i) the number of cations introduced into the lattice;
(ii) the ionic radius of the cations;
(iii) the valency of the cations;
(iv) the number of discontinuities in the network of silicon-oxygen tetrahedra;
(v) the O/Si ratio (the greater the ratio the lower the viscosity).

The effect of the ionic radius of univalent cations upon the viscosity shows a reversion with increasing ion concentration; thus potassium oxide at low concentration increases viscosity but at concentrations above $R_2O:SiO_2 = 1:1$ it lowers the viscosity to a greater extent than lithium oxide, which is ineffective in lowering viscosity both from ionic radius and from concentration considerations. Bivalent cations lower viscosity more than univalent cations.

At 1300°C., Li_2O 26 mol.-%, SiO_2 74 mol.-% has a surface tension of 332 dynes/cm.,[50] and Li_2O 36 mol.-% SiO_2 64 mol.-%, 334 dynes/cm. This increase in surface tension is contrary to the behaviour of potassium and sodium oxides and has been further demonstrated[51] in the systems Na_2O–SiO_2, Na_2O–CaO–SiO_2 and borosilicate glasses.

The partial molal surface tension of lithium oxide is 450 dynes/cm.[32]

The power factor (tan δ) has been measured on borosilicate glasses containing varying quantities of both lithium and sodium.[52] Increase in the Li/Na ratio caused increases in the power factor. Addition of lithium oxide to the Na_2O–Al_2O_3–B_2O_3–SiO_2 system gives glasses having very low values of loss angle measured at a frequency of 1 megacycle/sec.[34] A typical glass having a tan δ value of 0·0016 is: SiO_2 49·6, B_2O_3 20·8, Al_2O_3 9·0, Na_2O 13·9, Li_2O 6·7%.

Normal values for soda–lime–silica glasses are around 0·008.

In a study of the system Li_2O–Al_2O_3–SiO_2[53] the join Li_2O,SiO_2–β-eucryptite, $(Li_2O,Al_2O_3,2SiO_2)$ was shown to be a simple binary with a eutectic at 1070°C. containing 57% β-eucryptite. The refractive index of the glasses decreased from 1·560 to 1·546 with increasing β-eucryptite concentration. The phase equilibrium along the join SiO_2–β-eucryptite has been investigated with equipment controlling both temperature and pressure.[54] Eucryptite, spodumene and petalite could all be synthesized.

Some thermal expansion coefficients (in cm./cm./°C., at 30–500°C.) of lithium aluminium silicates are cited:[46]

$Li_2O,Al_2O_3,2SiO_2$	$76{\cdot}0 \times 10^{-7}$
$Li_2O,Al_2O_3,4SiO_2$	$66{\cdot}6 \times 10^{-7}$
$Li_2O,Al_2O_3,6SiO_2$	$52{\cdot}5 \times 10^{-7}$
$Li_2O,Al_2O_3,8SiO_2$	$43{\cdot}6 \times 10^{-7}$
$Li_2O,Al_2O_3,10SiO_2$	$39{\cdot}3 \times 10^{-7}$

$Li_2O,Al_2O_3,2SiO_2$ devitrified on cooling to 500°C.

Compositions near the ratio Li_2O–Al_2O_3–$2SiO_2$ always yield β-eucryptite when fired in air above 970°C. β-Eucryptite shows the unusual property of continuous thermal contraction from 1000°C. to room temperature.[56]

Phase equilibria in the system Li_2O–MgO–SiO_2[55] showed primary fields of crystallization of tridymite, cristobalite, $Li_2Si_2O_5$, Li_2SiO_3, $MgSiO_3$, Mg_2SiO_4 and a new compound, Li_2O,MgO,SiO_2. The primary field for this compound is mainly below the Li_2SiO_3–forsterite join.

The cordierite–spodumene join has been studied in the system Li_2O–Al_2O_3–MgO–SiO_2.[57] At high temperature the phase diagram shows a small region of solid solution on the cordierite side, appreciable solid solution on the spodumene side, and regions of three or four phases, including α-cordierite, mullite, spinel, corundum and β-spodumene. The liquidus has a minimum between 40 and 50% cordierite at 1347°C., rising to the melting points of spodumene at 1421°C. and cordierite at 1530°C.

The ternary system Li_2O–BaO–SiO_2 has been used[58] to confirm the theory of Dietzel,[33] who had predicted that no ternary compounds would be formed. Only the binary silicates of the partial systems Li_2SiO_3–SiO_2, Li_2SiO_3–$BaSiO_3$ and $BaSiO_3$–SiO_2 were identified. The invariant points are all eutectics with the characteristics shown below.

System	Melting Point (°C.)	Composition (%)
Li_2O,SiO_2–BaO,SiO_2	970	SiO_2 50, BaO 26, Li_2O 24
$Li_2O,2SiO_2$–$BaO,2SiO_2$	960	SiO_2 66·5, BaO 12, Li_2O 21·5
Li_2O,SiO_2–BaO,SiO_2–$2BaO,3SiO_2$	940	SiO_2 53, BaO 24·5, Li_2O 22·5
Li_2O,SiO_2–$Li_2O,2SiO_2$–$BaO,2SiO_2$	910	SiO_2 65·5, BaO 12·5, Li_2O 22
Li_2O,SiO_2–$BaO,2SiO_2$–tridymite	920	SiO_2 67, BaO 12, Li_2O 21

Refs. p. 156

Borate Systems.

The system Li_2O–B_2O_3 has been extensively studied. Melts containing up to 10% Li_2O give glasses on cooling.[34] Determinations of density in the range 600–1000°C. in the liquid system have been carried out by the counter-balanced-sphere method.[59] At room temperature there is a linear increase in density with the addition of lithium oxide up to approximately 30 mol.-%. At 800° and 1000°C. the increase is again linear but rising more steeply up to 15 mol.-% and showing a maximum at 30 mol.-%. Over the temperature range 25–1000°C. expansivity was high for low lithium oxide content, showed a minimum at 10% and then increased. In the low lithium oxide region expansivity in the liquid range decreased with increasing temperature, while in the high lithium oxide range, the reverse was true.

The refractive index also increases with lithium oxide content, while the molecular refraction and molecular volume decrease.[60] Lithium glasses exhibit straight-line functions for their properties and optical constants, and it is thought likely therefore that lithium ions enter the borate structure, filling gaps which are present in the lattice, without distortion.

Viscosity and electrical resistivity have also been determined.[61] Isotherms of log viscosity (η) in the range 700–800°C. showed a minimum in the low-alkali region and a maximum as the lithium oxide concentration increased. The electrical resistivity decreased rapidly with increasing lithium oxide content, with a corresponding rapid increase in the equivalent conductivity.

Surface tensions in this system have been measured by means of the pull exerted on a thin-walled platinum cylinder with its lower edge in contact with the liquid.[62] Lithium oxide raised the surface tension of the melt. Comparative figures (at 1000°C.) are:

B_2O_3	83·5 dynes/cm.
B_2O_3, 10·6% Li_2O	141·7 dynes/cm.
B_2O_3, 20·1% Li_2O	201·6 dynes/cm.

In the high-alkali range the effectiveness of the common alkalis in raising surface tension was Li > Na > K, whereas in the low-alkali range the order was reversed.

The dielectric loss of Li_2O–B_2O_3 glasses[63] is higher than that of similar soda or potash glasses. The value shows a minimum at approximately 9 mol.-% Li_2O.

In the system Li_2O–Al_2O_3–B_2O_3[64] the region of easily fusible glasses has been studied, and the following generalizations put forward:

(i) Lithium ions do not cause a contraction of glass in the whole-glass region, but only in the destruction region.

(ii) Devitrification takes place readily in the destruction region, where glass is being contracted, but only with great difficulty in the accumulation region.

(iii) The components of the devitrified glass are $LiBO_2$, $Li_2B_4O_7$ and $9Al_2O_3,2B_2O_3$.

(iv) Addition of alumina reduces thermal expansion only up to the transformation region; beyond this region expansion is increased. A substantial decrease in the coefficient of expansion is caused when the composition is $Li_2O,4B_2O_3$.

(v) The point of transformation and softening point are maximal at a ratio $Li_2O,2B_2O_3$ containing up to 10 mol.-% Al_2O_3.

(vi) The thermal coefficient of electrical conductivity is higher in the accumulation region than in the destruction region.

The system Li_2O–BeO–B_2O_3 forms the basis of Lindemann glasses. These glasses find application in the windows of *X*-ray tubes owing to their high *X*-ray transmittancy.[65] The absence of silica in these glasses makes them readily attacked by moisture in the atmosphere.

The densities of glasses in the system range from 2·014 to 2·271 and the refractive indices from 1·498 to 1·561.[66,67] Lithium oxide increased the density of the glass, and if the proportion of boric oxide was high, increased its chemical stability.[68] The softening point of these glasses is approximately 500°C. Typical glasses resistant to crystallization and transparent to *X*-rays are:

	(a)	(b)
BeO	14·1%	11·6%
Li_2O	17·5%	17·7%
B_2O_3	68·4%	70·7%

Crystallization of glasses of this type is thought to be due to the formation of $3BeO,B_2O_3$, $LiBO_2$ and $Li_2B_4O_7$.[69,66] Substitution of Na_2O or K_2O for Li_2O causes only small changes in density and refractive index[70] but reduces corrosion resistance.

Similar properties are shown by the system Li_2O–MgO–B_2O_3.[65,70] The densities are in the range 1·91–2·38 and the refractive indices 1·49–1·56, both increasing with magnesia content.[71]

Phosphate Systems.

The system Li_2O–P_2O_5 has been investigated.[72] Changes in density, refractive index, molar volume and molar refraction were found to be non-linear with additions of lithium oxide. The effect of adding this oxide to phosphate glasses was studied by plotting the Abbé number against increasing molar concentration.[73] A smooth curve resulted; this was interpreted as normal behaviour in that lithium ions were introduced into the lattice without breaking down the tetrahedral structure around phosphorus atoms.

Other Glasses.

Additions of lithium oxide to various barium or lead tellurite glasses have been reported.[74] These glasses have a very high refractive index and low softening point, together with very good infra-red transmission to beyond 5·5 μ. A typical glass has the composition TeO_2 81–92, PbO 5–18, Li_2O 1–3%. The addition of lithium oxide increases the expansion coefficient and reduces the deformation temperature, in this case to 270°C. The refractive index is 2·14, and glasses of this type have higher resistivity than the more common soda–lime–silica glasses.

Similar glasses obtained by substituting germanium for tellurium[75] again have their properties enhanced by additions of lithium oxide. An infra-red transmission of 20–35% at 6 μ, together with high opacity to *X*-rays and good resistance to chemical attack, is claimed.

Glazes and Enamels.

In addition to its wide application in the manufacture of glasses, lithium oxide frequently imparts desirable properties to enamels and glazes.

Substituting Li_2O for Na_2O on a molecular basis in vitreous enamels improved fusibility, gloss, opacity and gave increased resistance to gouge, abrasion and acid attack.[76] Substituting on a weight basis, however, increased fusibility and increased gloss slightly, but decreased resistance to gouge, abrasion and acid attack. A decrease in opacity was observed. The substitution of spodumene for felspar in these enamels gives the advantages of lithium oxide addition. High-grade lepidolite may also be used as a source of lithium oxide.[77]

Small additions of lithium oxide to ground-coat enamels for steel sheet in general raise the surface tension of the melt.[51] In enamels of this type many attempts have been made to reduce or dispense with the boric oxide content. Where this has been achieved lithium oxide may be employed to reduce surface tension.[78]

The effect of additions of lithium oxide to titania cover-coat enamels has also been investigated.[79,80] Replacement of 1 part of potassium oxide by 1 part of lithium oxide resulted in an increase in reflectance and decrease in fluidity. If 3 parts of lithium oxide replaced 1 part of potassium oxide, the reverse effect occurred. Additions of lithium oxide increased resistance to acids and to abrasion.

To obtain an enamel of high electric strength the alkali content, especially the lithium and sodium oxide contents, must be maintained as low as possible.[81]

Addition of lithium oxide to whiteware glazes in general sharply reduces surface tension, enabling the glaze to mature at a lower temperature. Improved gloss and general quality are reported.[51]

Lithium oxide is used in the production of monoclinic zirconium dioxide for opacifiers in paints and glazes.[82] The conversion of amorphous or tetragonal zirconia to monoclinic zirconia occurs above 600°C. Trace impurities cause discoloration and slagging. These difficulties are readily overcome by the addition of up to 5% Li_2O, which acts as a catalyst in the conversion.

Lithium oxide combined with strontium oxide has been found to be an excellent substitute for lead oxide in dinnerware glazes.

Phosphors.

An Al_2O_3–Li_2O–Fe_2O_3–SiO_2 phosphor is described.[83] It is efficiently excited by a 2537 A. radiation, emitting a band spectrum with its energy peak at 6800 A. A typical composition is Al_2O_3 84·1, Li_2O 7·5, SiO_2 8·2, Fe_2O_3 0·2%. After firing for 2 hr. at 1250°C., considerable quantities of lithium oxide can be leached out with acid without reducing the fluorescence, but the total absence of lithium causes complete loss of fluorescence.

Thermally stable phosphors may be protected by coating with a readily fusible glass.[84] A mixture of phosphor and finely divided low-melting glass is spread over a soda–lime glass and heated for 30 min. at 600–700°C. in an inert atmosphere. A suitable glass is of the composition: SiO_2 20, Al_2O_3 3, MgO 2, Li_2O 2, Na_2O 5, K_2O 2, B_2O_3 66%. In this way composite phosphor layers can be built up.

Semiconductors.

The mechanism of oxidation and corrosion processes in metals and alloys has been widely studied. Lithium oxide vapour has been found to inhibit the oxidation of nickel and cobalt and accelerate that of titanium.[85-87] This phenomenon is thought to be due to the change in defect concentration in the oxide layer caused by the formation of solid solutions with lithium oxide.

Nickel may be protected in this way by heating in lithium oxide vapour at 1000°C.[88] The rate of oxidation at higher temperatures is frequently determined entirely by the diffusion of ions and electrons through the products of oxidation. Lithium oxide becomes incorporated in the lattice and reduces the number of vacant Ni^{2+} sites and thereby the oxidation rate. The rate of reduction of nickel oxide to nickel by hydrogen is decreased by the presence of lithium oxide, owing to an increase in the activation energy.[89]

The electrical properties of compounds of the Li_2O–NiO type have been studied, with a result that they have been developed as semiconductors. It has been found that the specific resistivity of various metal oxides which are non-conductors in the pure state can be lowered considerably by incorporating foreign metal oxides into them. It is necessary for the ionic radius of the foreign metal to be similar to that of the parent, but that its ionic charge should differ by at least one unit from the parent metal ion.[87]

The change in lattice parameter caused by the introduction of the second oxide may be followed either by electron diffraction or by *X*-ray back-reflection.[90,91] Lattice expansion gives rise to *n*-type conductivity and lattice contraction to *p*-type. The addition of lithium oxide to nickel oxide results in lattice contraction; this is thought to be due to the formation of Ni^{3+} ions having an ionic radius of 0·35 A., against the 0·78 A. of both Ni^{2+} and Li^{+}.[92] An equation to account for the formation of Ni^{3+} has been put forward by Verwey:[90]

$$n\mathrm{Li_2O} + 2(1-n)\mathrm{Ni^{2+}O} + \tfrac{1}{2}n\mathrm{O_2} \rightarrow 2\mathrm{Li}_n\mathrm{Ni}^{2+}_{1-2n}\mathrm{Ni^{3+}}_n\mathrm{O}$$

In the formation of $NiO-Li_2O$ the colour changes from grey-green to black with increasing lithium content.[93] The addition of 10% Li_2O causes a drop in resistivity from 10^8 to 1 ohm/cm.[94] Intermediate resistivity values are:

0·0025%Li	9530 ohm/cm.
0·9%Li	1·27 ohm/cm.[95]

The conductivity of this system is independent of oxygen pressure, and is attributed to the considerable increase in the concentration of electron-deficient sites (Ni^{3+}). In the system $ZnO-Li_2O$ the increase in the concentration of quasi-free electrons is insufficient to produce oxygen-pressure independence.[96] The system $CoO-Li_2O$ behaves very similarly to the $NiO-Li_2O$ system.[87]

The conductivity of calcium oxide has been determined: Above an oxygen pressure of 10^{-2} mm. calcium oxide is a defect conductor, while below it, it is an electron-excess conductor. Additions of lithium oxide give defect conduction even in high vacuum.[97]

Semiconductors of the Li_2O-NiO and Li_2O-ZnO types may be used as catalysts in certain oxidation reactions. Addition of lithium oxide to the *n*-type conductor zinc oxide increases the activation energy for carbon monoxide oxidation, but decreases it for the decomposition of nitrous oxide. Addition of lithium oxide to the *p*-type nickel oxide has the opposite effects.[98]

Lithium vanadyl vanadates[30] are semiconductors (see p.149) having electrical conductivities in the region of 0·1 $ohm^{-1}cm.^{-1}$.

RADIATION CHEMISTRY

Some compounds in the system $Li_2O-Al_2O_3-SiO_2$ are satisfactory sources of positive ions.[99] The sample is heated to 900–1000°C. on a platinum strip in vacuum. The emission of current is thought to be due to a change in the ratio of ^6Li to ^7Li. The compound $3Li_2O,Al_2O_3,3SiO_2$ gave a current of 4×10^{-4} amp./cm.^{2} for 40 hr. Spodumene ($Li_2O,Al_2O_3,4SiO_2$) may also be used.

Lithium oxide has been bombarded with *α*-particles and deuterons.[100] The target was prepared by depositing lithium oxide on gold leaf. The following reactions were observed:

10-Me.V. deuteron bombardment:

$^{16}O\ (d, p)\ ^{17}O$	
$^{16}O\ (d, d)\ ^{16}O$	(higher energy level)
$^{16}O\ (d, \alpha)\ ^{14}N$	
$^{7}Li\ (d, p)\ ^{8}Li$	
$^{7}Li\ (d, d)\ ^{7}Li$	(higher energy level)
$^{7}Li\ (d, \alpha)\ ^{5}He$	

20-Me.V. *α*-particle bombardment:

$^{16}O\ (\alpha, \alpha)\ ^{16}O$	(higher energy level)
$^{7}Li\ (\alpha, p)\ ^{10}Be$	
$^{7}Li\ (\alpha, d)\ ^{9}Be$	
$^{7}Li\ (\alpha, t)\ ^{8}Be$	
$^{7}Li\ (\alpha, \alpha)\ ^{7}Li$	(higher energy level)
$^{6}Li\ (\alpha, \alpha)\ ^{6}Li$	(higher energy level)

SECTION VIII

LITHIUM HYDROXIDE

By R.E. OLIVER

Preparation and Production

Lithium hydroxide is formed by the action of water on lithium metal or lithium oxide according to the equations:

$$2Li + 2H_2O \rightarrow 2LiOH + H_2\uparrow$$

$$Li_2O + H_2O \rightarrow 2LiOH$$

Preparation by these methods is in general of academic interest only.

A simple laboratory mode of preparation is the double decomposition of lithium sulphate and barium hydroxide solutions.[1]

$$Li_2SO_4 + Ba(OH)_2 \rightarrow BaSO_4 + 2LiOH$$

If exactly equivalent quantities are used, a pure dilute solution of lithium hydroxide remains after filtration.

The preparation of lithium hydroxide on a small scale by electrolysis has been described.[2] A 30–35% solution of lithium chloride is electrolysed at approximately 10V. between a platinum anode and a mercury cathode. The cathode is circulated to maintain a concentration of 0·004% Li in the amalgam which is decomposed by water to give a dilute lithium hydroxide solution. Vigorous recycling of the electrolyte at a temperature of 45°C. gives a current efficiency of 95%. The product, though free from chloride, sulphate and iron, contains up to 2% of lithium carbonate.

Lithium hydroxide is a common starting material in the preparation of many lithium compounds. In recent years interest in lithium compounds has greatly increased, and this has resulted in the development of several new processes for the production of lithium hydroxide.

A widely used process is the causticization of lithium carbonate with lime.[3] The reaction proceeds according to the equation:

$$Li_2CO_3 + Ca(OH)_2 \rightarrow 2LiOH + CaCO_3\downarrow$$

The reactants are slurried together and boiled by means of steam. With 5% excess of slaked lime present and sufficient water to give a final concentration of 0·3lb. of lithium hydroxide per gallon, the conversion is nearly complete. The precipitated chalk is allowed to settle and the lithium hydroxide solution decanted. The solution is then evaporated and on cooling yields crystals of lithium hydroxide monohydrate.

The process described produces approximately 1 ton daily of lithium hydroxide monohydrate of 99% or greater purity. The plant is constructed in stainless steel. The major impurity in the product is lithium carbonate formed by the absorption of carbon dioxide from the atmosphere. Care is taken to exclude air wherever possible. The main disadvantage of the process appears to be the use of lithium carbonate as a starting material, which itself is the end product of a lengthy extraction process.

Lithium may be extracted direct from certain minerals as lithium hydroxide solution.

Spodumene ($Li_2O,Al_2O_3,4SiO_2$) is heated to 1100°C.[4] At this temperature β-spodumene is formed almost instantaneously and can be readily crushed to 200 mesh. The finely ground mineral, slaked lime and water are mixed in the ratio 1:2:5 and digested at 200°C. for 2hr. in an autoclave. The filtrate, dilute lithium hydroxide solution, contains approximately 85% of the lithium present.

A similar process is described[5] for the treatment of alkali aluminium silicates of the approximate composition SiO_2 50%; Al_2O_3 30%; Na_2O, K_2O, and Li_2O combined 15–20%.

Lithium hydroxide may also be extracted from spodumene by heating with lime and leaching with water.[4] Spodumene is converted to β-spodumene and finely ground. It is then mixed with 2·7 times its weight of finely ground limestone and heated to 1100°C. The sinter is reground and leached with boiling water. Up to 90% of the lithium present in the mineral is thus extracted as lithium hydroxide.

Petalite ($Li_2O,Al_2O_3,8SiO_2$) may also be treated in this way.

Physical Properties

Anhydrous lithium hydroxide crystallises in the tetragonal system,[6] the crystal parameters being a = 3·55A., c = 4·34A.

The unit cell consists of two molecules with Li^+ at 000 and ½½0 and OH^- at 0½u and ½0$\bar{u}$. The lattice parameter u = 0·20.

The lattice energy of the anhydrous salt calculated from the structure is 205kg.-cal./mole.[7]

When lithium hydroxide solutions are crystallized at room temperature lithium hydroxide monohydrate is produced. This salt crystallizes in the monoclinic system. Using Cu $K\alpha$-radiation[8] the axial ratios were found to be: a = 7·37A., b = 8·26A., c = 3·19A. The angle of inclination of 3rd. axis (β) = 110° 18′. The unit cell consists of four molecules, each Li^+ being at the centre of a tetrahedron of O^{--}. Two such tetrahedra share an edge in a reflection plane at an angle to the a axis Upper and lower corners of all tetrahedra are shared with tetrahedra in the cells immediately above and below, the edges between these shared corners being parallel to the c axis. Thus paired tetrahedra form unending chains in the c direction. O^{--} of the shared tetrahedral edges in the reflection planes are in OH^- groups and O^{--} in upper and lower tetrahedra are linked sideways by OH^- bonding between hydroxyl groups and water.

The scattering of light in hydroxide crystals in relation to the hydrogen bond has been studied spectrographically.[9] Light from a mercury vapour lamp is filtered, concentrated on the microcrystalline sample by means of a quartz condenser and projected on the spectrograph. Sharp lines for several hydroxides including anhydrous lithium hydroxide indicate no hydrogen bonding. A small increase in band width for the monohydrate indicated weak hydrogen bonding.

The density of lithium hydroxide monohydrate is 1·51g./c.c.[8]

The surface tension, density, viscosity and vapour pressure of aqueous solutions of lithium hydroxide are given in Tables I, II, III and IV.

TABLE I.- SURFACE TENSION OF AQUEOUS LITHIUM HYDROXIDE[10]

13·30	3·99	8·02
17·10	4·12	8·29
22·37	4·24	8·54
44·52	4·40	8·86
∞	4·57	9·20

Neutron capture by aqueous lithium hydroxide has been calculated from results obtained with boric acid solutions.[13] A radium-beryllium source is placed at the centre of a glass balloon containing first distilled water and then lithium hydroxide solution. The neutron density is determined as a function of the distance from the centre, and the difference is due to neutron capture by lithium.

The ratio of cross sections for neutron capture thus determined is $\sigma_{Li}/\sigma_H = 185$.

Lithium hydroxide monohydrate is readily decomposed by heat to yield the anhydrous salt. A dehydration study[14] has shown that no fractional hydrate exists between $LiOH,H_2O$ and LiOH.

The melting point has been reported as 462°C.[15] and 471·3°C.[16] The salt has also been reported to show polymorphism, the transition from the α to the β form taking place at 413°C.[15]

The equilibrium $2LiOH(s) \rightleftharpoons Li_2O(s) + H_2O(g)$ has been studied by dynamic diffusion[17] and by both transpiration and effusion methods.[18] Water vapour pressures obtained by the transpiration method (passing nitrogen over a heated sample) and the effusion method (water vapour being pumped off from a heated sample) are in good agreement: selected values are given in Table V.

These figures are approximately one hundred times greater than those obtained by the dynamic diffusion method and as yet this discrepancy is unexplained. Comparison of the values obtained from these figures and those calculated from the Third Law of Entropies show close agreement:-

	Experimental	Calculated
ΔH°	32•6kg.-cal.	32•8
ΔF°	22•5kg.-cal.	22•7
ΔS°	33•7 E.U.	33•85

TABLE V.- VAPOUR PRESSURE OF LITHIUM HYDROXIDE

Temp. (°K.)	Pressure (atm. × 10^7)
533	7•03
557	35•4
589	135•0
598	231•0
619	505•0
620	531•0
621	648•0

When introduced as an aqueous spray into an hydrogen-air flame, which could be made either oxidising or reducing, lithium hydroxide is reported to be stable up to 2300°K.[19]

Under these conditions the intensity of the resonance radiation emitted has been measured.[20] Lithium hydroxide was found to be the most stable of the alkali hydroxides and from the results obtained the collision diameter of the excited alkali atoms was calculated as $\sigma_{Li}^2 = 22 \times 10^{-16}$cm.^{2}.

The specific heat of a solution of 1 gram molecule of lithium hydroxide in 100 gram molecules of water is given as 0•9813.[21] The temperature coefficient of the specific heat is reported to be very small.

The heat of dilution of lithium hydroxide is reported as:-[21]

$LiOH,25H_2O$ + $25H_2O$ + 133g.-cal.
$LiOH,25H_2O$ + $75H_2O$ + 223g.-cal.
$LiOH,25H_2O$ + $175H_2O$ + 288g.-cal.
$LiOH,25H_2O$ + $375H_2O$ + 338g.-cal.
$LiOH,25H_2O$ to infinite dilution + 390g.-cal.

The work of dilution is given as:-[12]

Moles water per mole solute.	A_0°,g.-cal.	A_{10}°,g.-cal.
10•83	95	97
13•30	75	77
17•10	57	59
22•37	41	42
44•52	21	21
∞	0	0

The heat of neutralisation of lithium hydroxide[21] has been studied with a series of strong acids and strong bases at various concentrations. Extrapolation of the curves obtained to infinite dilution gave the value for the formation of water from OH^- and H^+. In all cases an almost constant value of $\Delta H = -13,693$ g.-cal./mole was obtained.

The apparent molar heat capacity (Φ_C)[22] for lithium hydroxide is found to be $\Phi_C = -19{\cdot}98 + 12{\cdot}53m^{1/2}$ where m = molality of the solution, while $\overline{Cp}_2$, the partial molar heat capacity of the solution, $= -19{\cdot}98 + 18{\cdot}80m^{1/2}$. These results agree fairly well with those of Richards and Rowe[21] who express some doubt regarding the purity of the lithium hydroxide used.

Experimental data have been summarized[23] and the following generalizations have been reached.

Φ_C is a linear function of $m^{1/2}$ for aqueous solutions of univalent strong electrolytes from infinite dilution to approximately $m = 2{\cdot}5$.

$\bar{C}p_2$ is a linear function of $m^{\frac{1}{2}}$. These relations are expressed by formulae:

$$\Phi_c = \Phi_c^\circ + Am^{\frac{1}{2}}$$

$$\bar{C}p_2 = \bar{C}p_2^\circ + \tfrac{3}{2}Am^{\frac{1}{2}}$$

$$\Phi_c^\circ = \bar{C}p_2^\circ$$

Over the range 18–25°C., A is constant at 17•9. At 25°C. $\Phi_c^\circ = -21{\cdot}6$, and $d\Phi_c^\circ/dT = \tfrac{2}{7}$ per degree. The heat capacity of a given solution in g.-cal. per gram of solution is given by

$$\bar{C}_p = \frac{1000 + m}{1000 + m\ \mathrm{M}}$$

(where M = molecular weight of solute).

Heat content data for aqueous solutions of lithium hydroxide have been converted to 18°C. and tabulated.[24] The extrapolation to infinite dilution is made by employing the Debye-Hückel theory of strong electrolytes. Typical results are given in Table VI where $\Phi_h - \Phi_h^\circ$ = the relative apparent heat content of the solute, and $\bar{H}_2 - \bar{H}_2^\circ$ = the relative partial molal heat content of the solute.

TABLE VI.- HEAT CONTENT DATA FOR AQUEOUS SOLUTIONS OF LITHIUM HYDROXIDE

Moles solute per 1000 grams H_2O	$\Phi_h - \Phi_h^\circ$ g.-cal. per mole solute	$\bar{H}_2 - \bar{H}_2^\circ$ g.-cal. per mole solute

1•44	362	525
1•96	418	615

Heat capacities of solid lithium hydroxide and lithium hydroxide monohydrate have been measured between 15 and 300°K.[25] Integration of the heat capacity curves gives the molal entropy values at 298•16°K.

LiOH	10•23 ± 0•05 E.U.
LiOH,H_2O	17•07 ± 0•05 E.U.

The change in entropy at 25°C. for the reaction LiOH,H_2O (cryst.) → LiOH (cryst.) + H_2O (liquid) obtained by Ueda[26] from data for the dissociation pressures of the hydrate and the heats of solution of the two crystals, combined with the value 10,520±3g.-cal. for the molal heat of vaporisation of water, is in good agreement with the ΔS_{25}° values[25] for the reaction LiOH,H_2O (cryst.) → LiOH (cryst.) + H_2O (gas) computed from experimental entropy values and the entropy of steam. This demonstrates the applicability of the third law of entropies to lithium hydroxide.

$$\mathrm{LiOH,H_2O\ (cryst.)} \rightarrow \mathrm{LiOH\ (cryst.)} + \mathrm{H_2O\ (liquid)}$$
$$\Delta H_{25}^\circ = 4{,}020 \pm 20\text{g.-cal.}$$
$$\mathrm{LiOH,H_2O\ (cryst.)} \rightarrow \mathrm{LiOH\ (cryst.)} + \mathrm{H_2O\ (gas)}$$
$$\Delta H_{25}^\circ = 14{,}540 \pm 23\text{g.-cal.}$$

Heats of formation [27] are:-

$$\text{LiOH}\ \Delta H^\circ_{25}\ -116{,}589 \pm 90\text{g.-cal./mole.}$$
$$\text{LiOH,H}_2\text{O}\ \Delta H^\circ_{25}\ -188{,}926 \pm 120\text{g.-cal./mole.}$$

Free energies of formation[27] are:-

$$\text{LiOH}\ \Delta F^\circ_{25}\ -105{,}676 \pm 130\text{g.-cal./mole}$$
$$\text{LiOH,H}_2\text{O}\ \Delta F^\circ_{25}\ -163{,}437 \pm 160\text{g.-cal./mole.}$$

The high temperature heat content and entropy of lithium hydroxide has been determined up to 900°K.[16] Samples were sealed in gold capsules and the determinations carried out in a drop calorimeter. The following equations were derived to fit the experimental results:-

LiOH (cryst.) (400 – 744·3°K.)

$$H_T - H_{298\cdot16} = 11\cdot988\,T + 0\cdot00412\,T^2 + 226{,}700\,T^{-1} - 4701\text{g.-cal.}$$
$$S_T - S_{298\cdot16} = 27\cdot603 \log T + 0\cdot00824\,T + 113{,}350\,T^{-2} - 72\cdot035\ \text{E.U.}$$

LiOH (liquid) (744·3 – 900°K.)

$$H_T - H_{298\cdot16} = 20\cdot74\,T - 3638\text{g.-cal.}$$
$$S_T - S_{298\cdot16} = 47\cdot76 \log T - 116\cdot859\ \text{E.U.}$$

The heat of fusion at 744·3°K. = 5010 g.-cal./mole.

The electrical conductance of aqueous lithium hydroxide solutions at 25°C. has been studied.[28] Over the concentration range 0·02703 moles/kg. of water to 0·001394 moles/kg. of water, the equivalent conductivity (Λ_C) rises from 223·1 to 232·5. A limiting value of 234·7 (Λ_0) is quoted. Later work[29] gives the limiting value as 237·2. Lithium hydroxide even at low concentrations appears to show considerable deviation from complete ionisation.

The conductance of certain non-aqueous solutions of lithium hydroxide is given in Table VII.[30,31]

TABLE VII.- CONDUCTANCE OF ALCOHOLIC SOLUTIONS OF LITHIUM HYDROXIDE

Litres solvent containing 1 gram molecule of solute	Molecular Conductivity		
	CH_3OH	C_2H_5OH	C_3H_7OH
2	24·35	-	-
4	34·15	7·2	-
8	42·83	9·45	-
16	50·92	12·0	-
32	58·32	15·35	4·15
64	64·96	18·3	5·33
128	70·25	22·0	6·8

512	77·69	28·11	-
	90·42	36·9	14·91

The *E.M.F.* was measured in the following cells.[32]

Pt. H_2 / LiOH / LiCl / AgCl / Ag
Pt. H_2 / LiOH / LiBr / AgBr / Ag

Combined figures gave the following values of dissociation constants for concentrations up to an ionic strength of 0·1.

Temperature	Dissociation Constant
5°C.	0·55 ± 0·02
15°C.	0·64 ± 0·02
25°C.	0·66 ± 0·02
35°C.	0·63 ± 0·01
45°C.	0·65 ± 0·02

Refs. p. 170

The spectral absorption of lithium hydroxide solutions of various concentrations has been determined.[82] Results over the range 1–3μ were compared with those of water and all curves showed a broad intense absorption band with a maximum at 2·29μ. This band was thought to be due to dissociated hydroxyl ions. Maximum absorption with water was observed at 1·48μ and 1·98μ. The effect of dissolving lithium hydroxide was to decrease the absorption of the band at 1·48μ by an amount proportional to the concentration of the solution.

Later workers[83,84] confirmed this work by finding a maximum at 2·30μ but discovered that the position of the water maximum changed in the presence of alkali. Alcohol solutions of alkalis were therefore studied and in all cases small bands occurred at 0·96μ 1·10μ and 1·27μ which were attributed to hydroxyl ions.

Solid Systems Containing Lithium Hydroxide.

Li, K || OH, Cl[33]

The binary system LiOH–KOH forms an incongruent melting compound, 2LiOH,KOH, which forms solid solutions with KOH with a minimum melting point of 227°C.

The system LiCl–KCl forms a eutectic at 325°C. containing 43 mole % KCl. In the system LiOH–LiCl a 1 : 1 compound is formed which gives with LiOH a eutectic melting at 262°C. and containing 37 mole % LiCl.

The equilibrium KOH + LiCl $\rightleftharpoons$ LiOH + KCl is shifted strongly in favour of LiOH–KCl. The diagonal section LiOH–KCl is stable.

The six invariant points are:-

Temp. °C.	Mole %				Solid Phases
	LiOH	KOH	LiCl	KCl	
Eutectic 228	30·0	64·0	-	6·0	γ-KOH, KCl, 2LiOH,KOH
Eutectic 280	43·5	-	45·0	11·5	LiCl, KCl, LiOH,LiCl
Eutectic 283	62·0	-	36·5	1·5	LiOH, KCl, LiOH,LiCl
Transition 311	58·5	38·5	-	3·0	LiOH, KCl, 2LiOH,KOH
Transition 310	21·0	69·5	-	9·5	β-KOH, KCl, 2KOH,KCl
Transition 347	22·0	65·0	-	13·0	2KOH,KCl, KCl, KOH,KCl

Li, K || OH, CrO_4[34]

In this system the equilibrium is strongly shifted in the direction of the more stable pair LiOH–K_2CrO_4.

In the binary system Li_2CrO_4–K_2CrO_4 there is a compound Li_2CrO_4,K_2CrO_4 m.p. 550°C., and eutectics containing 74 mole % Li_2CrO_4 m.p. 415°C. and 46 mole % Li_2CrO_4 m.p. 546°C.

In the binary system LiOH–Li_2CrO_4 there are two compounds, 4LiOH,3Li_2CrO_4 m.p. 430°C. and LiOH,Li_2CrO_4 m.p. 460°C.; also three eutectics containing 45 mole % Li_2CrO_4 m.p. 318°C., 64 mole % Li_2CrO_4 m.p. 427°C. and 78 mole % Li_2CrO_4 m.p. 450°C. The system LiOH–K_2CrO_4 is stable and represents a quasibinary system with a eutectic at 3·5 mole % K_2CrO_4 m.p. 468°C.

In the stable triangle LiOH–Li_2CrO_4–K_2CrO_4 there are three compounds, 4LiOH,3Li_2CrO_4, LiOH,Li_2CrO_4 and Li_2CrO_4,K_2CrO_4 and four invariant points which are.

Temp. °C.	Mole %		
	LiOH	Li_2CrO_4	K_2CrO_4
Eutectic 339	47·0	43·0	10·0
Eutectic 378	17·5	63·5	19·0
Transition 373	52·5	33·5	14·0
Transition 369	35·0	52·0	13·0

In the stable triangle LiOH–KOH–K_2CrO_4 there is a field of the compound

2LiOH,KOH and two invariant points.

Temp. °C.	Mole % KOH	Mole % LiOH	Mole % K_2CrO_4
Eutectic 200	69•0	25•0	6•0
Transition 335	38•0	60•0	2•0

Li, Na || OH, CrO_4[35]

The reaction of the system may be expressed by $2NaOH + Li_2CrO_4 \rightleftharpoons 2LiOH + Na_2CrO_4$ with the equilibrium shifted towards the more stable pair $NaOH-Li_2CrO_4$.

In the binary system NaOH–LiOH there are three transition points at 254, 238 and 299°C. with 57•0, 61•5 and 94•5 mole % NaOH. Two compounds of uncertain compositions are formed. The binary system $LiOH-Li_2CrO_4$ behaves as in the previous system.

In the stable triangle $LiOH-NaOH-Na_2CrO_4$ there are three fields of crystallization: LiOH,NaOH, $4NaOH,Na_2CrO_4$, and $2NaOH,Na_2CrO_4$. There are three transition points at 228, 270 and 304°C. and a eutectic at 221°C.

In the stable triangle $LiOH-Li_2CrO_4-Na_2CrO_4$ there are six fields of crystallisation, $4LiOH,3Li_2CrO_4$, $LiOH,Li_2CrO_4$, Li_2CrO_4,Na_2CrO_4, $4LiOH,Na_2CrO_4,3Li_2CrO_4$, and two polymorphic forms of Li_2CrO_4.

Li, K || OH, Br.[36]

This system has nine fields of crystallisation including the pure components and the compounds 2LiOH,LiBr and 2LiOH,KOH.

Li, K || OH, NO_3.[37]

The binary system $LiOH-LiNO_3$ has a eutectic at 40•5 mole % LiOH with m.p. 183°C. There is a compound $LiOH,LiNO_3$ decomposing at 195°C. The system has ten fields of crystallisation including the pure components and the compounds 2LiOH,KOH and $LiOH,LiNO_3$.

Liquid Systems Containing Lithium Hydroxide.

The solubility curve for lithium hydroxide in aqueous sodium hydroxide shows a minimum at 12•7N-NaOH as illustrated in Table VIII. Below this concentration the solid phase is $LiOH,H_2O$ and above it is LiOH.

TABLE VIII.- SOLUBILITY OF LITHIUM HYDROXIDE IN AQUEOUS SODIUM HYDROXIDE SOLUTIONS

Chemical Properties

The general chemistry of lithium hydroxide is well established. Reactions recently studied are summarised below:

In the reaction between nascent chlorous acid and lithium hydroxide,[41] an aqueous solution of chlorine dioxide, together with twice the stoicheiometric quantity of hydrogen peroxide, is added to a lithium hydroxide solution at 20°C. and the solution is allowed to remain at this temperature for 5hr. The main product is lithium chlorite, although considerable quantities of lithium chlorate are also formed.

Lithium hydroxide reacts in the cold with phosphoric acid to give either insoluble Li_3PO_4 or LiH_2PO_4, depending on the ratio of lithia to phosphate. Di-lithium hydrogen phosphate is not formed. Neither of the known salts is hydrated.[42,43]

Lithium hydroxide reacts with nitric oxide according to the following equations:[44]

$$2LiOH + 4NO \rightarrow N_2O + 2LiNO_2 + H_2O$$
$$4LiOH + 6NO \rightarrow N_2 + 4LiNO_2 + 2H_2O.$$

The reaction at room temperature is extremely slow and produces essentially lithium nitrite and nitrous oxide containing a little nitrogen. It is estimated that several years would be required for the reaction to go to completion. Rise of temperature greatly accelerates the reaction. At 280°C. the second reaction assumes greater importance, approximately 25% of nitrogen being found in the nitrous oxide. At this temperature the reaction goes to completion in approximately 24hr. Above 280°C. the study of the reaction is complicated by the decomposition of lithium nitrite.

Lithium hydroxide solutions react with freshly prepared gallium hydroxide.[45] If excess of gallium hydroxide is added to the boiling alkali solution, after filtration and evaporation hexagonal plates of $Li_2O,Ga_2O_3,12H_2O$ separate. This compound loses water even at room temperature and may be readily dehydrated over sulphuric acid or by gentle heating to give $Li_2O,Ga_2O_3,2H_2O$. Strong heating results in the formation of $LiGaO_2$.

The reaction of aqueous lithium hydroxide with arsenious oxide at 25°C. gives only $LiAsO_2$.[46]

Aqueous solutions of lithium hydroxide and boric acid react, depending on their ratio, to give the following salts:-[47,48]

$$Li_2O,5B_2O_3,10H_2O$$

stable above 40·5°C.

$$Li_2O,2B_2O_3,3H_2O$$

formed from a solution of the above salt below 40·5°C. or directly. Stable over the range 0–100°C.

$LiBO_2,8H_2O$ - stable below 36–9°C.
$LiBO_2,2H_2O$ - stable above 36–9°C.

Several reactions of lithium hydroxide with non-metals have been studied.[49]

Heating lithium hydroxide with sulphur gives hydrogen sulphide, lithium sulphide, lithium sulphite and lithium sulphate. Heating with selenium gives hydrogen selenide, lithium selenide and lithium selenate. With red phosphorus the products are phosphine and lithium phosphate. Mixtures of lithium hydroxide with sulphur, selenium or phosphorus are capable of reducing nitrates or nitrocompounds to ammonia.

The reaction of inorganic bases and tertiary amyl halides with lithium hydroxide has been studied.[50] The formation of the corresponding olefin increases with temperature and with hydroxide concentration. At 45°C., using lithium hydroxide, *tert.*amyl chloride gave a 17% yield of olefin.

The behaviour of lithium hydroxide towards trimeric phenylstibinic acid, $[(3Ph\ SbO_2)\ H_2O],nH_2O$, differs from that of sodium and potassium hydroxides.[51] The trimeric acid and its amino derivative are neutralised by 3 molecules of sodium or potassium hydroxide to give the salts of its monomer. Lithium hydroxide however neutralises only 1 molecule giving probably the salt of the monomer and excess acid in a dimeric form. Other substitution products are completely neutralised by all three alkalis.

In preparing glycylglycine,[52] the yield is markedly improved by substituting lithium hydroxide for sodium hydroxide.

In the base-catalysed reaction between phenol and formaldehyde[53] the rate of reaction is found to be less in the presence of lithium hydroxide than with sodium, potassium or barium hydroxides. This is thought to be due to the greater hydration of the lithium ion.

Two reactions of lithium hydroxide with citral have been studied polarographically:[54]

(i) decomposition with lithium hydroxide results in the formation of acetaldehyde and methylheptenone by cleavage.

(ii) lithium hydroxide catalyses the condensation of citral and acetone to pseudoionone.

Applications

Lithium hydroxide is manufactured on a very large scale and is widely used as a raw material for producing other lithium compounds.

It has found considerable application as an absorbent for gases and water vapour. A patent describes a preparation[55] where lithium hydroxide monohydrate is mixed with 20% of its weight of 20% sodium silicate solution. The mixture is moulded as required and heated to drive off water. The resulting mass, which is porous and does not become gummy in use, is capable of absorbing 76% of its weight of carbon dioxide in two hours. A similar preparation is described for use in submarines.[56] Lithium hydroxide has the advantage that carbon dioxide is removed readily from air at temperatures as low as −30°F. It is also used in submarines and ventilating systems in conjunction with sodium peroxide for the regeneration of respired air.[57] The constituents are ground together, a little water is added and the mixture compressed. After heating to expel water, the hard porous mass may be crushed to size. Two satisfactory mixtures are:

Na_2O_2	40 (parts by weight)	Na_2O_2	65
$LiOH,H_2O$	9	$LiOH,H_2O$	9½
$CuOCl_2$	½	$Ca(OH)_2$	1
		NiO	½

Lithium hydroxide behaves similarly to sodium hydroxide in the mercerization and xanthation of cotton fibres. It therefore finds some application in this field where limited variations in conditions and properties are required. The subject has been widely investigated.[58,59,60] It has been shown that while alkalis other than lithium hydroxide give addition compounds with cellulose in a stoicheiometric ratio,[61–64] no definite compounds with lithium hydroxide are observed. Of the alkalis, lithium hydroxide causes the greatest swelling.[65] Cellulose mercerized with lithium hydroxide may be xanthated in much the same way as with sodium hydroxide. Xanthates so formed however are not completely soluble in alkali.[66]

Lithium hydroxide when chlorinated yields lithium hypochlorite, which is a good textile bleach.[67] It can be purified and stored in the crystalline state without deterioration.

Lithium hydroxide is sometimes used in the tanning of hide.[68] It is absorbed to a greater extent than other alkalis, but causes less swelling.

Silica sols may be stabilized with lithium hydroxide[69] added as a solution to the sol in the molar ratio SiO_2:LiOH 5:1. The mixture immediately sets to a firm gel, which disperses spontaneously to a fluid sol after 17hr. Such sols are used in the preparation of catalysts, phosphors and phosphor adhesives and also in the treatment of leather, paper and textiles.

Lithium hydroxide is a usual additive to the electrolyte of alkaline storage batteries. The efficiency of a battery of this type decreases with the life of the nickel anode. By adding lithium hydroxide to the potassium hydroxide it is possible to increase the anode capacity by 40% for a given cell (50g. of lithium hydroxide per litre gives an increase of approximately 22%).[70] This is thought to be due to the increase in oxygen overvoltage caused.[71,72] The carbonate concentration of the electrolyte is maintained substantially lower by the deposition of insoluble lithium carbonate.[73]

Additions of lithium hydroxide to cracking catalysts are often made to alter their selectivity.[74] A silica–alumina catalyst of composition SiO_2 89·5% Al_2O_3 10·0% and H_2O 0·5% may be rendered inactive for the cracking of hexadecane by the addition of lithium hydroxide. The same addition however renders it more active for the cracking of di-*iso*butylene. A high proportion of its activity for cracking cumene is retained after the lithium hydroxide treatment. A similar effect is observed with catalysts for cracking cetane.[75] It is thought that lithium hydroxide and other alkalis neutralise different acidic active sites effective in the cracking of hydrocarbons.

Alloys of the type Al 40%, Cu 55%, Zn 5% or Al 40%, Cu 50%, Zn 5%, Ni 5% are treated with strong aqueous alkalis to give Raney type catalysts.[76] Aluminium dissolves and the granular powders formed readily dehydrogenate *cyclo*hexanol to *cyclo*hexanone, but are inactive in the dehydration of *cyclo*hexanol to *cyclo*hexene. Preparation by means of lithium hydroxide gives catalysts active for both reactions.

Short chain hydrocarbons may be synthesized from carbon monoxide and hydrogen using supported iron catalysts.[77] A solution of ferrous chloride is added to a lithium carbonate slurry prepared *in situ* from lithium hydroxide and ammonium carbonate, further ammonium carbonate is added and the mass washed free from chloride.

Lithium hydroxide may be used as an alternative to potassium hydroxide in the alkali activated production of water gas from steam and coal.[78]

The crevice corrosion of stainless steel couples in water up to 600°F. has been investigated.[79] The formation of iron oxide was retarded by small additions of lithium hydroxide to the water.

Wax type esters may often be solubilised by means of their metal soaplike reaction products.[80] These can readily be dissolved in normal solvents to form varnishes, lacquers etc. Lithium hydroxide and Japan wax are cited as an example.

A preparation[81] for the manufacture of porous cement has been patented. A slurry containing lithium hydroxide, casein and bentonite is added in small quantities to the cement mixture.

Refs. p. 170

Analytical

A 1% lithium hydroxide solution containing 5% of potassium nitrate may be used as a substitute for yellow ammonium sulphide in the separation of the copper and arsenic groups.[85] The sulphides of arsenic, antimony and tin readily dissolve while those of the copper group are insoluble, though mercuric sulphide begins to dissolve slowly on boiling. The reagent is cheaper and more pleasant to use than yellow ammonium sulphide.

SECTION IX

LITHIUM PEROXIDE

By R.E. OLIVER

PREPARATION AND FORMATION

A small-scale preparation of lithium peroxide is described[1] in which $Li_2O_2,H_2O_2,2H_2O$ is prepared as an intermediate compound. Lithium metal (2 g.) is dissolved in absolute alcohol (250 ml.). Lithium ethoxide, which separates, is filtered and washed with absolute alcohol. The ethoxide is then suspended in absolute alcohol (250 ml.) and treated with 30% hydrogen peroxide (25 ml.). After stirring for several hours the mixture is filtered in a carbon-dioxide-free atmosphere. A 56% yield of $Li_2O_2,H_2O_2,2H_2O$ results, which is dehydrated over phosphorus pentoxide at 20 mm. pressure, to give lithium peroxide.

A similar preparation is described in a recent patent.[2] A lithoxy-compound such as an alcoholate, is treated with the stoichiometric proportion of aqueous hydrogen peroxide. An organic liquid such as propyl or allyl alcohol forming an azeotropic mixture with water is added, and the mixture distilled. It is claimed that a 95% recovery of almost pure lithium peroxide is obtained by filtration of the residual organic phase.

Lithium peroxide is formed in considerable quantities in the course of a number of reactions. Anhydrous lithium nitrate[3] is added to liquid ammonia contained in a trap cooled in solid carbon dioxide. A sodium superoxide is added, and the mixture stirred while the ammonia is allowed to evaporate. Reactions of the type:

$$LiNO_3 + NaO_2 \rightarrow Li_2O_2 \text{ (35\% yield)}$$
$$LiNO_3 + 2NaO_3 \rightarrow Li_2O_2 \text{ (29\% yield)}$$

occur; by-products, including the normal oxide, amide, nitrite and hydroxide, are also formed.

Lithium metal may be dissolved in liquid ammonia[4] to give a blue solution. If oxygen is passed through the solution is becomes colourless. On evaporating the ammonia a residue containing 23% of Li_2O_2 and 77% of Li_2O remains.

The action of oxygen on lithium amalgam gives a mixture containing approximately 30% of Li_2O_2 and 70% of Li_2O.[5]

PHYSICAL AND CHEMICAL PROPERTIES

Until recently it was thought that lithium peroxide crystallized in the tetragonal system.[1,6,7] The most recent investigations[8] have shown it to be hexagonal, with $a = 6{\cdot}305$ A., $c = 7{\cdot}710$ A. The unit cell contains 8 molecules.

The density of lithium peroxide has been determined.

2·26 g./c.c. at 25°C.[1]
2·297 g./c.c. at 25°C.[8]

The melting point has also been determined:

425°C.[9]
460°C.[10]

Lithium peroxide is unstable under normal conditions of temperature and pressure, but may be kept for short periods at low temperatures in the absence of light.[1]

The dissociation temperature (760 mm.) is 195°C.[9] The dissociation pressures (Table I.) of lithium peroxide at various temperatures have been determined by a dynamic method.[10]

TABLE I.- DISSOCIATION PRESSURES OF LITHIUM PEROXIDE

Temp. °C.	p (mm.)
43	5
54	12
87	47
93	66
116	122
127	184
148	271
181	497
198	790

The heat of dissociation is +13·6 kg.-cal.[10] The heat of formation is +144·8 kg.-cal.[9] An α to β transformation is reported to take place at 225°C.[11]

LITHIUM FLUORIDE

By A. B. TRENWITH

In the preparation of lithium fluoride interest has centred on the production of large single crystals from which optical components, particularly for infrared apparatus, may be fabricated.

Two common procedures for synthesizing lithium fluoride are the neutralization of lithium bicarbonate solution by hydrofluoric acid[1] and the double decomposition between lithium chloride and ammonium fluoride solutions.[2,3]

Of the methods used for preparing crystals from the pure material that devised by Stockbarger,[1,5] involving slow cooling of the melt, produces satisfactory specimens, particularly when the operation is carried out in a vacuum furnace. Optical lithium fluoride has also been prepared by a procedure devised by Kyropoulos[4,5] in which crystallization is initiated by a crystal seed and the crystal is cooled at a very slow rate. Some modifications of the above procedures have been employed.[6,7] An investigation of the properties of synthetic lithium fluoride crystals[8] has shown that wide variations occur and that vacuum-grown crystals are generally the most suitable for use in optical systems. Traces of impurity in the lithium fluoride cause a marked deterioration in the optical properties of the final crystal. One method of purification[9] involves treatment of the powder with fluorine for long periods at elevated temperatures.

Lithium fluoride has a face-centred cubic lattice. The lattice constant determined by electron diffraction[10] is $a = 4{\cdot}015 \pm 0{\cdot}002$A. For crystal sizes of less than 100A. the lattice constant decreases slightly with crystal size. The internuclear distance and dipole moment determined by molecular beam spectroscopy[11] are 1·51A. and 6·6 Debye units respectively. Quantum mechanical computation of the lattice energy[12] gives a value of 239 kg.-cal./mole (as against the experimental value 240 kg.-cal./mole) and the surface energy of a (100) face at 0° abs. is found to be 557 ergs/sq.cm.[13]

The lithium–fluoride bond has a greater covalent character than any other alkali metal–fluoride bond; a value of 11% covalent character has to be introduced into calculations of binding energy, internuclear distance and dipole moment to bring the results into line with experimental data.[14]

The density of the solid fluoride determined by the temperature-of-flotation method[15] is $d_{25} = 2{\cdot}63905 \pm 0{\cdot}0001$ and the coefficient of linear expansion[15] up to 380° is $\alpha_t = 0{\cdot}0_4 3376 + 0{\cdot}0_7 2054t + 0{\cdot}0_{10} 4885t^2$. Owing to the suitability of lithium fluoride as a material for making optical windows and spectroscope prisms the optical properties for the ultra-violet and infra-red regions have been studied in detail.[16-20] Values obtained for the elastic constants by measurement of ultrasonic velocities[21] and by the study of reflexions of diffuse X-rays[22] show only fair agreement. In studying the effect of pressure on crystalline solids,[23] lithium fluoride was found to show no distortion up to 4000 kg./sq. cm.; it would therefore be a suitable material for optical windows in high pressure apparatus.

Determination of the refractive index of lithium fluoride at 21° in the visible region[24] yields $n_F = 1{\cdot}394810$; $n_D = 1{\cdot}392057$ and $n_C = 1{\cdot}390862$. The temperature variations of the refractive index measured between 0° and 400° for the wave-lengths 2537A., 3650A., 4358A., 5461A. and 5893A. are given in Table I.[25]

TABLE I.- TEMPERATURE VARIATIONS OF REFRACTIVE INDEX FOR LITHIUM FLUORIDE AT VARIOUS TEMPERATURES

Temp. °C.	$dn/dt \times 10^5$				
	2537A.	3650A.	4358A.	5461A.	5893A.
50	-1·10	-1·20	-1·25	-1·27	-1·27
100	-1·31	-1·37	-1·42	-1·44	-1·44
150	-1·45	-1·54	-1·60	-1·61	-1·60
200	-1·67	-1·75	-1·81	-1·81	-1·82
250	-2·00	-1·95	-2·01	-2·03	-2·03
300	-2·23	-2·20	-2·25	-2·26	-2·27
350	-2·44	-2·51	-2·56	-2·56	-2·58
400	-2·65	-2·78	-2·80	-2·82	-2·85

Taking the heat of formation of HF gas to be 65·0 kg.-cal., the heat of formation of lithium fluoride is 144·7 kg.-cal.[26] The Debye temperature drops steadily from 646 at 0°C. to 606 at −197·6°C. and then rises rapidly with further decrease in temperature, a value of 750 being obtained at −254·4°C.[26a] The heat content[27] from 0°C. to the m.p. (848°C.) is given by:-

$$H_t(s) - H_0(s) = 2{\cdot}26938t + 8{\cdot}6291(10^{-5})t^2 - 1{\cdot}01322(10^{-7})t^3 + 1{\cdot}6845(10^{-10})t^4 - 451{\cdot}849 \log\{(t + 273{\cdot}16)/273{\cdot}16\}$$

and from the melting point to 896°C. by:-

$$H_t(1) - H_0(s) = 657{\cdot}48 + 2{\cdot}50101t.$$

The standard entropy S°_{LiF} at 25°C. = 8·52 g.-cal./mol.

The heat of dissociation of lithium fluoride vapour determined by an optical method[28] is 78·4 ± 2·5 g.-cal. in comparison with the thermochemical value of 71·25 g.-cal.

The thermal conductivity of a single crystal[29] varies linearly with temperature over the range 100°–500°C., values of 0·00613 and 0·0138 g.-cal.sec.$^{-1}$ cm.$^{-2}$ °C.$^{-1}$cm. being obtained at 105° and 499°C. respectively.

Electrical conductivity measurements[30] show that at the melting point a single crystal of lithium fluoride has a conductivity of 0·6 × 10^{-2} ohms^{-1}cm.$^{-1}$ Just below the melting point the conductivity varies exponentially with the reciprocal of the absolute temperature. Lithium fluoride crystals have a dielectric constant of 9·27 ± 0·02 at 20°C.,[31] the coefficient of temperature variation[32] being 3·75 × 10^{-4}.

Of the binary systems containing lithium fluoride which have been studied those which form simple eutectics are recorded in Table II.

TABLE II.- BINARY SYSTEMS CONTAINING LITHIUM FLUORIDE WHICH FORM SIMPLE EUTECTICS

System	M.p. of eutectic (°C.)	Mole-% LiF	Ref.
$LiF-MgF_2$	742	67	33
	735	64	34
LiF–NaF	652	61	35
$LiF-CaF_2$	–	–	36
LiF–LiCl	484	30·5	37
$LiF-Li_2CO_3$	608	49	38
$LiF-Li_2MoO_4$	617	38	39
$LiF-Li_2WO_4$	642	38	39

In the system $LiF-Li_2CrO_4$ the compound Li_3CrO_4F is formed.[39] Another system giving rise to compound formation is $LiF-BaF_2$ which yields[37] $LiBaF_3$ also formed in the system $LiF-BaO$.[38] This compound which is cubic (a = 3•988A.) has an inverted perovskite structure and melts with decomposition at 850°C. The system $LiF-AlF_3$ yields Li_3AlF_6, m.p. 790°C.[39] On adding beryllium fluoride to lithium fluoride the temperature of crystallization is lowered, approaching the peritectic point at 461°C. and 38•5% BeF_2; at this temperature the compound Li_2BeF_4 is formed. With further increase in the concentration of beryllium fluoride the transition point is reached at 353°C. and 52•0% BeF_2 and as a result of the peritectic reaction the compound $LiBeF_3$ is formed; this compound is unstable, decomposing to yield Li_2BeF_4. A third compound $LiBe_2F_5$ corresponding to 66•7% BeF_2 decomposes at 277°C. without melting.[40,41] A thermal investigation of the system $LiF-LiBO_2$ indicates the formation of the compound $Li_3BO_2F_2$.[42] Evaporation of mixed solutions of lithium fluoride and aluminium fluoride yields colloidal solutions of the salt $Li_5Al_2F_8$.[43]

The crystal growth of lithium fluoride deposited from the vapour phase on various substrates has been examined by electron diffraction. On amorphous substrates[44] films thinner than 100A. showed completely random structure, but as the thickness increased the crystals showed a definite preferred orientation. A definite orientation was also observed on silver,[45] on other alkali halides,[46,47] on calcium carbonate,[48] on sodium nitrate[48] and on mica substrates.[49]

The heat and free energy of hydration of lithium fluoride are[50] 238 and[51] 219 kg.-cal. per mole respectively. It is the least soluble of the alkali metal fluorides, a fact attributable to the high lattice energy of the crystal. Its solubility in water increases over the temperature range 0°–35°C. from 0•1203 to 0•1354 g./100g. of water.[52] The solubility–temperature curve must reach a maximum between 35° and 198°C. since solubility measurements in the region 198°–375°C. show a decrease in solubility with increase in temperature from 0•1081 to 0•0222 g./100g. of solvent.[53] The solubility in water above its critical point remains practically constant with temperature at a solvent density of approx. 0•36. The solubility increases with temperature for higher densities and decreases with rising temperature for lower densities.[53]

Although only slightly soluble in water, lithium fluoride dissolves readily in liquid hydrogen fluoride. Over the temperature range −23° to 12°C. the solubility is virtually constant at 10•3g. LiF per 100g. HF.[54] The salt $LiHF_2$ formed in this system is unstable, losing hydrogen fluoride at room temperature in the solid state.[55] The formation and subsequent decomposition of $LiHF_2$ thus provides a means of preparing pure hydrogen fluoride.

The current–voltage curves for aqueous solutions of lithium fluoride at 25°C. show two breaks,[56,57] the first at 1•61V. and the second at 2•95V. The former is taken to correspond to the primary decomposition of water and the second is taken to be the decomposition potential of the salt.

Lithium fluoride is not hygroscopic and has a slight acid reaction; consequently it is a suitable material for use as a flux in a number of processes. It is used as a constituent of aluminium welding fluxes[58] and brazing fluxes for zirconium and titanium,[59] and as a fluxing agent in the sintering of such refractory materials as alumina, thoria and beryllium oxide,[60] magnesium-lithium alloys[61] and metallic beryllium.[62] Lithium fluoride is the most powerful known mineralizing agent in the mullitization process.[63]

Lithium fluoride has been used as a catalyst for the combined dehydrogenation and dehydration of ethyl alcohol. Dehydrogenation is the predominant reaction with this catalyst.[64] Other miscellaneous uses of lithium fluoride include the determination of cyclotron beam energies[65] by measurement of the depth of penetration of a yellow colour produced in a lithium fluoride crystal, and its use as a shadow-coating agent in electron microscopy.[66] The amount of light reflected from a glass surface may be reduced by coating with a thin suspension of finely ground lithium fluoride in a water-soluble organic solvent such as alcohol;[67] petroleum lubricating oils may be decolorized by contact with powdered lithium fluoride;[68] finely divided lithium fluoride has been found to be efficient in preventing explosions in methane-air mixtures;[69] the stability of boric oxide glasses is improved by adding 1 mole of lithium fluoride with each 0·5 to 10 moles of boric oxide;[70] lithium fluoride crystals have been used as *X*-ray crystal monochromators, an intense multiple reflexion being produced on exposing a natural cleavage surface to an *X*-ray beam.[71]

SECTION XI

LITHIUM CHLORIDE

By R. E. OLIVER

PREPARATION AND PRODUCTION

Solutions of lithium chloride may be readily prepared in the laboratory by dissolving either the hydroxide or the carbonate in hydrochloric acid. Lithium chloride is also formed by the direct combination of the elements, or by the dissolution of the metal, oxide or silicate in hydrochloric acid. The anhydrous salt is obtained only with difficulty by evaporation of a solution, as the concentrated solutions are extremely corrosive and the anhydrous salt deliquescent.

Anhydrous lithium chloride may be prepared by solvent extraction with amyl alcohol. In one method described[200] a saturated aqueous solution of lithium chloride is treated with excess dioxan. Approximately half the lithium chloride separates as $LiCl,H_2O,(C_2H_4)_2O_2$. The solid is desolvated at reduced pressure, the temperature being raised gradually to 150°C. A residue of pure anhydrous lithium chloride remains.

Production from lithium carbonate is carried out on a large scale.[1] The damp carbonate containing approximately 8–12% of water is treated with hydrochloric acid in a rubber-lined vessel. The slightly acid solution (*d* 1·2) is freed from sulphate with barium chloride; excess acid is removed with lithium carbonate and barium with sulphuric acid. The solution is then made slightly alkaline with lithium hydroxide and evaporated. A solid lithium chloride containing only 1% of water is prepared by passing the solution down a ceramic tower against rising flue gases.

Patent specifications[2,3] describe a development of this technique whereby fused mixtures of lithium oxide and lithium chloride (present in practice as hydroxide or carbonate and near-anhydrous chloride) are passed down a heated tower against a chlorinating agent such as hydrogen chloride, carbon and chlorine, carbon monoxide and chlorine, or phosgene, to give the fused anhydrous chloride.

Many processes have been developed for the recovery of lithium chloride from minerals. In a process using spodumene[4] and similar lithium-containing silicates[5] the mineral is sintered with calcium sulphate and calcium carbonate for 2–3 hr. at 1100°C. The roasted product is cooled and leached with aqueous calcium chloride solution. Lithium, sodium and potassium dissolve as chlorides. Sulphate present in the solution is again removed with barium chloride, and barium and calcium with lithium carbonate. The solution is then evaporated; sodium and potassium chlorides are almost insoluble in concentrated lithium chloride solution and are precipitated. The final purification step, to remove the last traces of sodium and potassium, is to extract with hot 2-ethylhexanol, in which only lithium chloride is soluble, re-extract into water, and evaporate to dryness.

A patent process[6] describes the volatilization of lithium chloride from aluminosilicate minerals by heating with carbon in a stream of chlorine.

Another volatilization technique has been applied to minerals of the spodumene type.[7] 100 parts of calcined spodumene containing 1·2% of Li were ground to 200 mesh and mixed with 25 parts of anhydrous calcium chloride. The temperature was raised to 1050°C. and the pressure reduced to 5 mm. of mercury. Over a period of eleven hours the temperature was raised to 1150°C. and the pressure reduced to 2·5 mm. The condensate was estracedt with alcohol. A recovery of 96·5% of the lithium as lithium chloride is claimed. A similar process[9] describes the recovery of the lithium chloride by electrostatic precipitation.

Low-grade lithium minerals such as pegmatite ores containing 30% of spodumene may be concentrated by flotation and similarly treated.[8]

Lithium chloride may be recovered in high yield by volatilization from lepidolite.[10] The charge is heated to a temperature as near as practicable to the melting point of lepidolite (935°C.) and hydrogen chloride is passed over. A substantial excess of hydrogen chloride was found to be necessary, but a nearly theoretical recovery is claimed after 13 hr. Anhydrous lithium chloride was recovered from the cooler zones and a solution from the hydrochloric acid scrubbing towers.

Dilithium sodium phosphate, Li_2NaPO_4, is recovered as a by-product in the evaporation of liquors from Searles Lake, California. A patent specification[11] describes the conversion of this residue to lithium chloride. The salt is treated with slaked lime in an autoclave heated with steam at 100 lb. per sq. in. The reaction may be represented by the equation:-

$$2Li_2NaPO_4 + Ca(OH)_2 \rightarrow Li_4Ca(PO_4)_2\downarrow + 2NaOH.$$

The insoluble double calcium phosphate is filtered and washed. It is then treated with calcium chloride in an autoclave heated with steam at 50 lb. per sq. in.:-

$$Li_4Ca(PO_4)_2 + 2CaCl_2 \rightarrow 4LiCl + Ca_3(PO_4)_2\downarrow.$$

The lithium chloride solution is separated by filtration.

A patent specification describes the treatment of lithium-containing ores with hydrofluosilicic acid.[12] A water-soluble salt, Li_2SiF_6, is formed, which is decomposed by alkalis according to the equation:-

$$Li_2SiF_6 + 6NaOH \rightarrow 6NaF\downarrow + Si(OH)_4\downarrow + 2LiOH.$$

The solution is filtered and neutralized with hydrochloric acid.

A process is described for the recovery of lithium chloride in the preparation of lithium aluminium hydride.[206] The reaction of lithium hydride, aluminium chloride and ether gives a solution of lithium aluminium hydride and lithium chloride, which separates as an impure solid. The residue is heated in vacuum or an inert atmosphere between 30°C. and 650°C. The reactions, in order of occurrence with increasing temperature, are:-

(i) removal of ether;
(ii) $AlH_3.O(C_2H_5)_2 \rightarrow Al$, H_2 and $(C_2H_5)_2O$;
$LiAlH_4 \rightarrow Al$, H_2 and LiH;
(iii) NH_4Cl reacts with Li and Al compounds to give LiCl, $AlCl_3$, H_2 and ammonia;
(iv) $AlCl_3$ volatilizes with some NH_4Cl and LiCl;
(v) $AlCl_3$ volatilizes, leaving LiCl.

PHYSICAL PROPERTIES

Structure.

Anhydrous lithium chloride has a cubic structure of the sodium chloride type. It has been shown that lithium chloride crystallizes in this form whether obtained from solution, the vapour phase or a fused system.[13]

The unit cell contains 4 molecules and at 25°C. has $a = 5{\cdot}1396$ A.[14] Earlier work[15] gave the unit cell dimension at 25°C. as 5·12952 ± 0·00004 A.

Determinations of the lattice constant of lithium chloride by electron diffraction gave results agreeing to within 1·5% with those obtained by *X*-ray methods.[16] The growth of lithium chloride deposited from the vapour phase on cleavage surfaces of lithium fluoride, sodium chloride, potassium chloride and potassium bromide has been studied by electron diffraction. It was found in all cases that the crystallographic axes were parallel to those of the substrate.[17] Similar experiments involving deposition on muscovite showed a mismatch of 30% for lithium chloride.[18]

Early work by Hendricks[19] on the structure of lithium chloride monohydrate showed it to be tetragonal. This has more recently been confirmed[20] and the lattice constants calculated as $a = 5{\cdot}410$ A., $c = 3{\cdot}81$ A.

Molecular Volume.

The molecular volume of lithium chloride is 20·53.[21]

The absolute contraction constant, defined as the ratio of the molecular volume to the sum of the atomic volumes of the elements, is 0·69.[22]

The apparent molecular volume (Φ) of LiCl was determined at 18·1°C. and 0·5 M. LiCl concentration in water/organic-solvent mixtures (see Table I).[201]

TABLE I.- APPARENT MOLECULAR VOLUMES OF LITHIUM CHLORIDE AT 18·1°C. IN 0·5 M. SOLUTIONS

4·222	1·0888

Coefficient of Linear Expansion.

For anhydrous lithium chloride the value is $44{\cdot}76 \times 10^{-6}$.[14,15]

Compressibility.

The compressibility of anhydrous lithium chloride has been determined at pressures up to 12,000 atm.;[25] the value at 30°C. is $3{\cdot}41 \times 10^{-12}$, and an error of less than 1% is claimed.

The compressibility of aqueous lithium chloride solutions over the pressure range 0–1000 bars has been studied.[26] It was found that the compression was a linear function of the square root of the concentration only in extremely dilute solution.

At higher pressures (100–300 megabars) the results in Table II have been obtained.

TABLE II.- COMPRESSIBILITY OF AQUEOUS LITHIUM CHLORIDE SOLUTIONS

100·2	56·3
120·2	56·9
140·3	57·6
155·6	58·3

Other values[30,31] are in close agreement.

The transition $LiCl,2H_2O \rightarrow LiCl,H_2O$ takes place at 19·1°C., and the transition $LiCl,H_2O \rightarrow LiCl$ at 93·55°C.[29,32]

The solubility of lithium chloride in water decreases with increasing pressure.[33]

Solubility in Liquid Ammonia, Methyl Alcohol, Acetone and Quinoline.
See Tables IV, V,[38] VI,[43] and VII,[47] respectively. More recent work[39] on methyl alcohol has confirmed that the solubility is independent of temperature, but gives the solubility at 25°C. as 41·0 g. of LiCl per 100 g. of MeOH.[40] Earlier work on acetone[44] gave consistently higher solubilities.

Solubility in Diacetone Alcohol.[45]

$S = 0{\cdot}06683 - 0{\cdot}000395t + 0{\cdot}00001636t^2$, where S is the weight of anhydrous salt dissolved at t°C. in 1 g. of solvent.

Solubility in Other Solvents.

Some individual solubility values in miscellaneous solvents are collected in Table VIII.

In addition, lithium chloride is reported to be appreciably soluble in *iso*-amyl alcohol,[42] and very sparingly soluble in methyl *iso*butyl ketone.[45]

TABLE VIII.- SOLUBILITY OF LITHIUM CHLORIDE IN MISCELLANEOUS SOLVENTS

Solvent	Temp. °C.	Solubility	Reference
Liquid sulphur dioxide	25·00 ± 0·02	0·00062 g./100 g. solution	36
Phosphorus oxychloride	20	0·05 g./l.	37
Ethyl alcohol	25	24·7 g./100 g. EtOH	41
n-Propyl alcohol	25	16·0 g./100 g. PrOH	41
n-Butyl alcohol	25	12·2 g./100 g. BuOH	41
Acetonitrile	18	0·15 g./100 g. MeCN	40
Acetonitrile	25	0·14 g./100 g. MeCN	40
Formic acid	18	26·6 g./100 g. HCO_2H	40
Formic acid	25	27·5 g./100 g. HCO_2H	40
Tetrahydrofuran		Approx. 2 g./100 ml. solvent	46

Vapour Pressure.

A platinum-iridium crucible has been used to determine the vapour pressure of fused lithium chloride.[48]

Temp. °C.	Pressure, mm.Hg
1169	144
1247	276
1333	542
1384	770

More recent work[49,50] has been concerned with the rate of volatilization of lithium chloride in gas streams. Samples weighing 0·25 g. were maintained at 550°C. for 1 hr. in the stream.

Gas flow	% Loss in weight
Air	0·48
10 l./hr. HCl	0·08
6 l./hr. water vapour	0·90

At 800°C. the rate of evaporation of the chloride increases in the order Li, K, Rb, Cs and Na, and also with increase in the polarity of the gas used.

Vapour Pressures of Aqueous Solutions.

The vapour pressure of water above saturated solutions of lithium chloride has been determined (Table IX; the last value is from ref.[29], the remainder from ref.[51]).

The volatility of lithium chloride from an aqueous 0·1N. solution is reported to be nil.[52]

TABLE IX.- VAPOUR PRESSURES OF SATURATED LITHIUM CHLORIDE SOLUTIONS

Temp. °C.	Pressure, mm.Hg
23·90	2·63
29·90	2·93
34·90	5·32
39·90	7·26
44·90	9·82
54·84	16·70
80·15	37·9
100·30	78·3
119·85	173·9
140·05	334·4
160·30	615·4
180·20	1035·8

The water activity a_w for saturated lithium chloride at 25°C. is given by the expression:-[53]

$$a_w = p/p_0 = 0{\cdot}1105,$$

where p = vapour pressure of the solution and p_0 the vapour pressure of water at the same temperature.

The relation between temperature and the relative humidity over saturated lithium chloride solution has been determined[54] (Table X).

TABLE X.- RELATIVE HUMIDITIES OVER AQUEOUS SOLUTIONS SATURATED WITH LITHIUM CHLORIDE ($LiCl,H_2O$)

Temp. °C.	% Relative Humidity
0	14·7
10	13·3
20	12·4
30	11·8
40	11·6
50	11·4

Vapour Pressures of Lithium Chloride-Methylamine Complexes.[55] (Temperatures (T) are in °K.).

$LiCl,CH_3NH_2 \rightarrow LiCl + CH_3NH_2$, for the range 45–125°C.;

$$\log p_{mm.} = 11{\cdot}5113 - 2656{\cdot}5/T$$

$LiCl,2CH_3NH_2 \rightarrow LiCl,CH_3NH_2 + CH_3NH_2$, for the range 25–100°C.;

$$\log p_{mm.} = 10{\cdot}8484 - 2604{\cdot}6/T$$

$LiCl,3CH_3NH_2 \rightarrow LiCl,2CH_3NH_2 + CH_3NH_2$, for the range 10–95°C.;

$$\log p_{mm.} = 9{\cdot}7460 - 2147{\cdot}5/T.$$

Surface Tension of Aqueous Solutions and Fused Salt.

The surface tension of aqueous solutions of lithium chloride has been determined by the drop-weight method.[56]

Concentration (moles salt/l.)	σ (dynes/cm.)
1·08	74·74
1·94	76·22
3·51	79·46

The effect of hydrochloric acid on the surface tension of aqueous lithium chloride has been studied;[57] the acid reduces the surface tension, the effect increasing with increasing lithium chloride concentration.

The surface tension of fused lithium chloride at 750°C. is 127 dynes/cm.[58]

Viscosity of Aqueous Solutions.

Relative viscosities of aqueous lithium chloride and lithium chloride in dilute hydrochloric acid,[24] compared with pure water, have been determined (Table XI).

TABLE XI.- RELATIVE VISCOSITY OF LITHIUM CHLORIDE SOLUTIONS

Aqueous LiCl (25°C.)		Aqueous LiCl (25°C.) in 0·1018 M-HCl	
Wt. Molarity	Rel. Visc.	Wt. Molarity	Rel. Visc.
0·2235	1·0342	0	1·0070
0·7300	1·1075	0·2526	1·0415
1·798	1·2761	0·5001	1·0788
4·222	1·7391	1·0015	1·1556
		2·002	1·3168
		4·135	1·7282

The effect of temperature has also been studied (Table XII).[59]

TABLE XII.- EFFECT OF TEMPERATURE ON RELATIVE VISCOSITY OF LITHIUM CHLORIDE SOLUTIONS

Temperature	35·5°C.		45·3°C.		54·9°C.
Concentration (molal)	Rel. Visc.	Concentration (molal)	Rel. Visc.	Concentration (molal)	Rel. Visc.
0·319	1·0424	0·318	1·0416	0·318	1·0394
0·102	1·0118	0·102	1·0076	0·102	1·0045
0·032	1·0045	0·032	1·0028	0·032	1·0011
0·016	1·0020	0·019	1·0015	0·019	1·0006

It has been shown[60] that very thin films of aqueous lithium chloride behave as perfect fluids to within 0·1°C. of the f.p. The viscosity of the film is the same as that of the liquid in bulk. Gas viscometers of the Rankin type have been used for measuring the absolute viscosity of liquids;[61] for 12·03N. lithium chloride a value of 0·09017 ± 0·0007 has been obtained.

Diffusion in Aqueous Solutions.

Experimental methods for the determination of diffusion coefficients have been extensively studied by Harned.[62,63] It is now possible both by the conductance method, involving a measurement of change of concentration by means of a change of conductance in a diaphragm cell, and the Guoy layer interference method, involving the interference phenomena accompanying the deflection of light by gradients of refractive index, to study the Nernst theory as developed by Onsager and Fuoss.[64] Some data for lithium chloride are listed in Table XIII.

The effect of the presence of other ions including the lithium ion on the diffusion rate of the hydrogen ion has been investigated.[67] It has been shown that hydrogen ions may be almost stopped or accelerated as much as 40% above their normal velocity.

The diffusion of lithium chloride in sugar solution has been studied.[68] In the range 0·25–2·0M. sugar there is a steady decrease in the diffusion coefficient. In 2M. sugar solution the relative velocities of diffusion for alkali halides are in the order:-

$$LiCl > NaCl > KCl,$$

which is the reverse of the sequence for pure water.

TABLE XIII.- DIFFERENTIAL DIFFUSION COEFFICIENTS FOR AQUEOUS LiCl AT 25°C. (Selected values)

Concentration (moles LiCl/l.)	Diffusion Coefficient (cm.^{2}/sec. × 10^{-5})	Ref.
0 (Nernst limiting value)	1·368	
0·000634	1·348	65
0·00235	1·335	
0·00568	1·319	
0·0110	1·313	
0·05	1·280	66
0·10	1·269	
0·50	1·278	
1·0	1·302	
2·0	1·363	
3·0	1·430	

Thermodynamic Properties.

Heat of Formation.

For the reaction:-

$$Li + \tfrac{1}{2}Cl_2 \rightarrow LiCl,$$

$\Delta H^{\circ}_{298} = -91{,}612$ kg.-cal.[69] A more recent determination[70] by direct chlorination of lithium gives the value $-94{,}800 \pm 0{\cdot}6$ kg.-cal.

Heat of Solution and Heat of Dilution.

The heat of solution of lithium chloride in water has been determined at various concentrations.

Concentration of LiCl		Heat of Solution
0 (infinite dilution)	[71]	+8·570 kg.-cal. (20°C.)
0·0427 moles/l.		+8·476 kg.-cal. (20°C.)
0 (infinite dilution)	[72]	+8·765 kg.-cal. (25°C.)
0·08 moles/l.	[73]	+8·740 kg.-cal. (25°C.)
19·92 moles/l.	[72]	+0·600 kg.-cal. (25°C.)

The differential heat of solution diminishes with increasing salt concentration much more rapidly than with the other alkali metal chlorides.

A study has been made[74] of the integral heat of dilution of lithium chloride in water and in deuterium oxide. The values for water were slightly greater at all concentrations. Similar studies on the differential heat of dilution showed the results to be almost identical.

Heat of Solution in Methyl Alcohol.

Five determinations[71] between 0·0070 moles/l. and 0·0495 moles/l. gave a value at infinite dilution of +12·38 kg.-cal./mole, at 20°C.

Heat of Solution in Ethyl Alcohol.

Three determinations[71] between 0·0072 moles/l. and 0·0158 moles/l. gave a value at infinite dilution of +12·93 kg.-cal./mole, at 20°C.

Heat of Dissociation.

It has been shown[75] that the heat of dissociation of lithium chloride may be calculated from the frequency of the first absorption maximum in the ultra-violet of the solid and of solid chlorine.

Heat Capacity, Heat Content and Specific Heat.

The apparent molal heat capacity (ϕ_c) has been determined[76] for aqueous solutions at 25°C. (Table XIV).

TABLE XIV.- APPARENT MOLAL HEAT CAPACITY OF AQUEOUS LITHIUM CHLORIDE SOLUTION

Concentration (m) (moles/l.)	ϕ_c (Selected av. values) (in g.-cal.)	Specific Heat (g.-cal. per g.)
0·0400	−16·8	0·9976
0·0897	−15·3	0·9948
0·1600	−13·7	0·9911
0·2504	−13·1	0·9863
0·4904	−12·0	0·9739
1·0000	−10·3	0·9494
2·4614	−7·41	0·8890

A large quantity of experimental data has been summarized[77] and the following generalizations reached. ϕ_c Is a linear function of $m^{1/2}$ for aqueous solutions of univalent strong electrolytes from infinite dilution to approximately $m = 2·5$. $\overline{C}p_2$ (the partial molal heat capacity of the solute) is also a linear function of $m^{1/2}$. These relations are expressed by the following formulæ:-

$$\phi_c = \phi_c^0 + Am^{1/2};$$
$$\overline{C}p_2 = \overline{C}p_2^0 + {}^3/_2Am^{1/2};$$
$$\phi_c^0 = \overline{C}p_2^0.$$

Over the range 18–25°C., A is constant at 6·1. At 25°C. $\phi_c^0 = -16·2$, $d\phi_c^0/dT = {}^2/_7$ per degree C.

Heat content data for aqueous solutions of lithium chloride have been converted to 18°C. and tabulated.[78] The extrapolation to infinite dilution is made by employing the Debye-Hückel theory of strong electrolytes. Values of $\phi_h^{18} - \phi_h^0$ (the relative apparent heat content of the solute) and of $\overline{H}_2^{18} - \overline{H}_2^0$ (the relative partial molal heat content of the solute) are listed in Table XV.

TABLE XV.- RELATIVE APPARENT HEAT CONTENT AND RELATIVE PARTIAL MOLAL HEAT CONTENT OF LITHIUM CHLORIDE IN AQUEOUS SOLUTION

Moles LiCl per 1000 g. water	$\phi_h^{18} - \phi_h^0$ (g.-cal./mole solute)	$\overline{H}_2^{18} - \overline{H}_2^0$ (g.-cal./mole solute)
0	0	0
0·01	41	61
0·04	78	113
0·09	112	159
0·16	141	197
0·25	168	234

0·64	245	347
1·00	297	433
1·44	355	537
1·96	419	658

Energy of Hydration.

The sum of the standard free energies of hydration of pairs of ions[79] is

Σ (LiCl) = 191·8 kg.-cal./mole.

Work of Polarization.

The work of polarization w is the change in electrostatic energy resulting from the removal of a positive or negative charge from a lattice point in an ionic crystal.[80] With a rigid lattice of the rock-salt type it is assumed that the removal is effected so rapidly that there is no displacement of any ion as a whole.

Ionic polarizabilities:-

α_+ (10^{-24}cm.^{3}) w_+ 3·14 e.V.

α_- (10^{-24}cm.^{3}) w_- 1·89 e.V.

Activity Coefficient.

The activity coefficient of lithium chloride has been calculated from e.m.f., vapour pressure and freezing point data[81] (see Table XVI).

TABLE XVI.- ACTIVITY COEFFICIENT OF LITHIUM CHLORIDE IN AQUEOUS SOLUTIONS

Molality (Selected values)	γ (0° C.) Freezing point method	γ (20° C.) Vapour pressure method	γ (25° C.) (e.m.f. method)
0·001	0·96	–	0·965
0·005	0·93	–	0·927
0·01	0·91	–	0·901
0·05	0·85	–	0·819
0·10	0·81	0·791	0·779
0·20	0·78	0·756	0·750
0·30	0·77	0·739	0·739
0·50	–	0·731	0·736
1·00	–	0·754	0·753
3·00	–	–	1·165

Values at higher concentration[82] are as follows:-

Molarity	γ (25° C.) (Isopiestic method)
5	1·98
10	9·36
15	31·50
20	61·70

Isoactive Concentration.

This is defined as the concentration of a salt solution in which the water activity coefficient is equal to that in pure water.[91] For lithium chloride at 25°C. the value is 0·70 molal.

Accurate measurements have been made of the activity of lithium chloride in aqueous solutions containing both lithium and cæsium chlorides;[83] the system showed marked deviations from simple behaviour.

Activity coefficients have been determined by radiochemical measurements on lithium chloride solutions containing potassium chloride and radioactive ^{24}Na, which were equilibrated with ion-exchange resins at 25°C.[84]

The change in activity coefficient of lithium chloride in water-methanol mixtures at various concentrations is similar in form to the corresponding change in aqueous lithium chloride[85] (Table XVII).

The graph of activity against square root of molal concentration drops in each case to a minimum at $\sqrt{m} = 0{\cdot}7$.

TABLE XVII.- ACTIVITY COEFFICIENT OF LITHIUM CHLORIDE IN METHANOL-WATER MIXTURES

(Activity coefficients are referred to the value 1·00 at infinite dilution in each solvent mixture.)

Solvent	γ in 0·5 molal LiCl	γ in molal LiCl
H_2O	0·73	0·77

0·20	0·0330
0·40	0·0245
0·60	0·0212

Activity in *iso*Amyl Alcohol.

This has been found[92] from the distribution coefficient of lithium chloride between *iso*amyl alcohol and water in the range 8·6–0·15 M/1000 g. water solution. The values agree with those derived by the Debye–Hückel theory.

Activity in Formamide.

The melting points of formamide solutions of lithium chloride have been determined.[87] By assuming the cryoscopic constant for formamide to be 3·166 the following results were obtained.

Concentration (moles LiCl/kg. formamide)	γ
0·02	0·942

continued on following page.

Concentration (moles LiCl/kg. formamide)	γ
0·10	0·929
0·50	1·009
0·80	1·107

Activity in Acetonitrile.[88]

The activity coefficient of lithium chloride in acetonitrile has been determined from measurements of the e.m.f. of lithium-amalgam drop electrodes in double concentration cells using acetonitrile as electrolyte.

Miscellaneous Activity Data.

The phase diagram of the system LiCl–KF has been studied[89] and the activity of the components calculated (see Table XX).

TABLE XX.- ACTIVITY COEFFICIENTS OF LITHIUM CHLORIDE IN MIXTURES WITH POTASSIUM FLUORIDE

Transport Number, Dissociation and Solvation.

The transport numbers of the alkali chlorides at a given concentration are in the order Li < Na < K. This is unexpected in that the lightest ion, Li^+, would be expected to have the highest velocity; the anomaly is caused by the greater hydration of the Li^+ ion in solution.

Values of the transport number have been measured by the Hittorf method; selected values are given in Tables XXII and XXIII.

In a given solvent the degree of solvation of lithium chloride decreases with increase in concentration. At a given concentration the solvation decreases with the complexity of the solvent molecule.[94] Hydration numbers have been calculated from determinations of the salting-out of oxygen from aqueous solution by the addition of lithium chloride:-[95]

LiCl (0°C.) 23
LiCl (20°C.) 21.

The hydration number of the lithium ion in lithium chloride solution, extrapolated to infinite dilution, is $X_{Li^+} = 26{\cdot}9$.[96] By a cryoscopic determination, the hydration of the ions in molar and 0·5 M. lithium chloride, respectively, at 15°C., correspond to $LiCl, 15H_2O$ and $LiCl, 17{\cdot}8H_2O$.[97] A method for establishing the degree of hydration of LiCl is described,[204] in which aqueous solutions of lithium chloride are extracted with 2-octanol. The results are represented diagrammatically in Fig. 1.

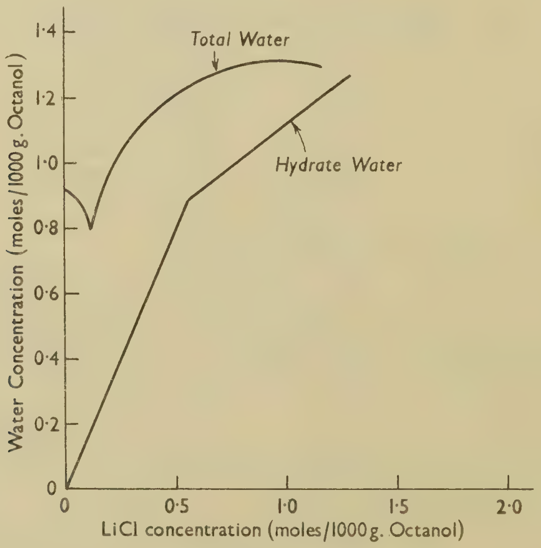

FIG. 1. HYDRATION OF LITHIUM CHLORIDE EXTRACTED FOR AQUEOUS SOLUTIONS BY OCTANOL

The solvation of lithium chloride in aqueous solutions of organic acids has been studied.[98] The degree of solvation increased with increasing numbers of carbon atoms, but decreased with increasing numbers of carboxyl groups. Solvation of lithium chloride in the system $H_2O-C_2H_5OH$ has been studied.[99] Ions remain solvated with water molecules until the proportion of ethyl alcohol exceeds 20 moles per cent.

Solvation of Lithium Chloride in Acetone.

Over the ranges 0·004–0·274 mole/l. at 18°C. and 0·008–0·271 mole/l. at 25°C., the solvation number was 5·14 to 5·57.[100]

Dissociation of Lithium Chloride.

Transference and conductivity measurements have been made for 0·05 N. solutions of sodium chloride and lithium chloride in water/methanol mixtures.[101] In a given solvent the Cl^- ion conductivities of the two salts are nearly identical, in accordance with the view that the solutes are completely dissociated. Lithium chloride has been shown to be a strong electrolyte in anhydrous acetic acid.[102]

The Raman spectra of salts in concentrated hydrochloric acid solutions have been studied.[103] No Raman scattering other than that of water is observed with aqueous lithium chloride solution up to 13 N. Aqueous hydrochloric acid (16·2 molal) containing the chloride (4 or 5 molal) gave a sharp Raman line at 2866 $cm.^{-1}$, indicating the presence of undissociated LiCl molecules.

Conductivity.

The specific conductance of fused lithium chloride has been determined by several workers.[104-107] Fairly close agreement is reported by the first three workers (Table XXIV).

In one case[105] a platinum–rhodium crucible was used, and attack is reported to have occurred above 783·3°C. When a platinum crucible was used[107] in an attempt to obtain results in the 780–930°C. range, much higher values of *K* were recorded.

The equivalent conductivity has also been determined (Table XXV).

TABLE XXV.- EQUIVALENT CONDUCTIVITY OF FUSED LITHIUM CHLORIDE

The electrical conductivity of anhydrous lithium chloride has been studied between −180°C. and its melting point.[108] Ohm's Law is obeyed, and the dependence of conductivity on temperature is in agreement with Vant Hoff's equation. Conductance data for the system LiCl–KCl are given in Tables XXVI and XXVII.

The conductivity of aluminium bromide rises sharply when lithium chloride is dissolved in it;[111] on electrolysis of the solution aluminium separates at the cathode and bromine at the anode.

In the system $LiCl–CdCl_2$[112] the phase diagram indicates the formation of intermediate phases in the solid state, and the equivalent conductivity isotherm shows marked negative deviations from linearity; this is thought to indicate that the mixtures in the melt are more covalent than the pure compounds.

Conductivity in Aqueous Solutions.

Conductivity data for dilute aqueous lithium chloride solutions are listed in Table XXVIII. An equation representing Λ in terms of concentration (up to 0·1 N.) has been proposed by Fuoss and Onsager.[116] At higher concentrations and temperatures the values in Table XXIX have been obtained.[117]

A complete formula to cover the range up to saturation has been derived by Falkenhagen and Leist.[118]

Conductivity of Aqueous Mixtures.

Conductivities have been determined for aqueous lithium chloride solutions containing hydrochloric acid,[24] methanol,[10] ethanol,[120] and pyridine;[121] for data, see Tables XXX to XXXIII, respectively.

Measurements of the conductivity of solutions of lithium chloride and sucrose at 20° C. showed that Walden's Law ($\lambda\eta$ = const.) was not obeyed, the value of this product increasing with increase in sucrose concentration.[119]

	(A limiting value of 90·9 is given.)					

Further work has been done more recently[126] which indicates that the Debye–Hückel limiting law holds for solvents of low dielectric constant (including *cyclo*hexanol) if the Bjerrum ion association is taken into account.

Nitromethane containing Aluminium Bromide.

Aluminium bromide dissolves readily in nitromethane to give a colourless solution in which lithium chloride is readily soluble. The presence of the chloride raises the specific conductivity of the mixture considerably, and during electrolysis lithium separates at the cathode.[127]

Ethyl Bromide containing Aluminium Bromide.

A similar system $LiCl-AlBr_3-C_2H_5Br$, has been studied[128] and has similar properties. For the system $AlBr_3-C_2H_5I$[203] addition of lithium chloride decreases the conductivity if the $AlBr_3 : C_2H_5I$ ratio is 0·24. At ratios above 0·44 the conductivity is raised by lithium chloride. Electrolysis of the mixture gives aluminium crystals.

N-Methylacetamide.[205]

Determinations were carried out between 30 and 60°C., in which range the dielectric constant of the solvent varied between 178·9 and 138·6. Results over the concentration range 5×10^{-4} M.–2 M. indicated the complete dissociation of lithium chloride; some data are given below.

Temp. °C.	Λ_0	$\Lambda_0\eta$
30	14·1	0·550
40	18·1	0·548
50	22·4	0·543
60	27·4	0·536

Hydrogen Cyanide.

Anhydrous hydrogen cyanide is a powerful dissociating medium for lithium chloride. The conductivity of solutions has been studied in the range 0·002 N. to 0·0001 N. at 18°C. A limiting value (Λ_0) of 345·5 has been derived.

Phosphorus Oxychloride.

The solubility of lithium chloride in anhydrous phosphorus oxychloride is 0·05 g./l. at 20°C. At this concentration the specific conductivity (κ) is $6{\cdot}6 \times 10^{-6}$ ohms^{-1}cm.$^{-1}$.[37]

Decomposition Potential.

The decomposition potential of fused lithium chloride at 800°C.[130] is 3·17 V. (extrapolated to zero current). Earlier workers[131] obtained rather higher figures. For the system $LiCl-AlBr_3$ the decomposition potential is 1·60 V.[111]

The fused system LiI–LiCl has also been investigated;[134] the iodine overvoltage is independent of lithium iodide concentration between 25 and 100% LiI.

Decomposition Potential in Methyl Alcohol.[132]

A sharp break in the current-voltage curve at 1·20 V. indicated the decomposition potential. A second break at 1·90 V. was thought to be due to traces of water. The e.m.f. of the cell:-

$$\text{Li} \mid 0{\cdot}01\ \text{N. LiCl in } CH_3CN \mid 0{\cdot}01\ \text{N. } AgNO_3 \text{ in } CH_3CN \mid \text{Ag}$$

is 2·476 V. at 25°C.[133]

Dielectric Constant.

The value for anhydrous lithium chloride (10·62 at 18°C., measured at 1800 m. wave-length) has been obtained by immersing the salt in a liquid between the plates of a condenser; the nature of the liquid was varied until the total capacity was not changed by the presence of the salt.[135]

In aqueous solution the value has been obtained by the Fürth ellipsoid method.[136] The graph of dielectric constant against lithium chloride concentration falls from infinite dilution to a minimum value of 73·5 at 7 N., recrosses the value for water at 15 N. and then continues to rise steadily. An explanation of the variations has been attempted[137] in terms of ordering of the solvent molecules around the solvated ions.

Magnetic Susceptibility.

Values for anhydrous lithium chloride at 20° C.:-

$$-\chi_m \times 10^{-6} = 24{\cdot}2^{138}$$

$$-\chi_m \times 10^{-6} = 24{\cdot}6.^{139}$$

In aqueous solution at 20° C.:-

$$-\chi_m \times 10^{-6} = 24{\cdot}2^{140}$$

$$-\chi_m \times 10^{-6} = 24{\cdot}3.^{138}$$

The same value has been obtained for solutions in 94·2% C_2H_5OH.

The variation of specific susceptibility with concentration has been been determined at 29° C.[141]

LiCl (%)	$-\chi_m \times 10^{-6}$ (selected values)
4·12	0·716
9·66	0·712
16·28	0·707
22·59	0·696
32·80	0·679
44·49	0·665

The complete plot of the figures shows that two lines may be drawn, giving molecular susceptibility constants over two concentration ranges:-

0–19% LiCl, $-\ 27 \times 10^{-6}$

28–44% LiCl, $-\ 25{\cdot}4 \times 10^{-6}$.

Miscellaneous Physical Properties.

(i) Refractive Index of anhydrous lithium chloride, 1·663.[14]

(ii) Molecular Refraction.

The molecular refraction of aqueous lithium chloride solutions was determined in the concentration range 2·77–43·87% LiCl and between 6° and 70° C. Extrapolation of the graph gave a figure of 7·76 for the D line (25° C.) for 100% LiCl.[142]

(iii) Infra-red Absorption.[143]

By use of a quartz cell and monochromatic radiation the following results were obtained with aqueous 6 N. lithium chloride:-

	Wave-length (μ)					
	52	63	83	100	117	152
Reflecting power (% R)	11·20	12·73	13·28	13·39	13·40	14·40
Absorption Coeff. (*na*)	0·43	0·48	0·41	0·35	0·32	0·35
Index of Refraction (*n*)	1·87	1·96	2·04	2·08	2·09	2·15

(iv) Dipole Moment.

For the isotopic pair ^{6}LiCl and ^{7}LiCl the difference in dipole moment is 1·8 millidebyes.[144]

(v) Soret Coefficient.

The coefficients of 0·05 N. lithium chloride at various temperatures are as follows:-[145]

Temp. °C.	30	40	50	60
Soret Coefficient	0·31	0·28	0·96	1·27

(vi) Coefficient of Internal Friction.

The following values are given:-[146]

650°C. $\eta \times 10^2 = 3{\cdot}02$

850°C. $\eta \times 10^2 = 2{\cdot}10$.

SYSTEMS CONTAINING LITHIUM CHLORIDE (WITHOUT WATER OR ORGANIC COMPOUNDS)

Three-Component Systems.

(i) Li, Be || Cl[147]

In the cooling curve there is a maximum at 360°C. indicating the compound Li_2BeCl_4. A eutectic melting at 300°C. contains 0·56 mole $BeCl_2$ and 0·44 mole LiCl.

(ii) Li, Hg || Cl[148]

The maximum solubility of LiCl in $HgCl_2$ is 1·9 mole-%. A eutectic mixture melting at 278°C. contains 1·6 mole-% LiCl. The boiling temperature of the mixture is 297°C.

(iii) Li || Cl, BO_2[149]

LiCl is completely dissociated in $LiBO_2$.

Four-Component Systems.

(i) Li, Ag || Cl, SO_4[150]

The stable diagonal AgCl–Li_2SO_4 is a binary characterized by the practically complete insolubility of the components indicated by a straight line at 818°C. from 2–98·8% Li_2SO_4. The unstable diagonal LiCl–Ag_2SO_4 consists of six crystallization branches. In the triangle AgCl, Li_2SO_4, Ag_2SO_4 there is a triple eutectic, m.p. 290°C. The thermal effect of the system is high (17·80 kg.-cal./equiv.) with a pronounced shift of equilibrium to the stable pair Li_2SO_4 and AgCl.

(ii) Li, Ag || Cl, NO_3[151]

The diagonal AgCl–$LiNO_3$ is a stable system of almost complete miscibility. The diagonal $AgNO_3$–LiCl was studied up to 82 mole-% LiCl (m.p. 484°C.); above this concentration LiCl decomposed the melt. Conjugate liquid phases appear between 26% and 77% LiCl at 325°C. and 456°C. The diagonal AgCl–$LiNO_3$ divides the system into two ternaries, $LiNO_3$–AgCl–LiCl (having a triple eutectic at 250°C. containing 0·5% AgCl and 87·5% $LiNO_3$) and $LiNO_3$–AgCl–$AgNO_3$.

(iii) Li, Ca || Cl, SO_4[152,153]

The eutectics of the binaries in this system are:-

LiCl–Li_2SO_4	480°C.	(52·5 mole-% Li_2SO_4)
LiCl–$CaCl_2$	475°C.	(53 mole-% $CaCl_2$)
LiCl–$CaSO_4$	533°C.	(25 mole-% $CaSO_4$)

$CaCl_2$-Li_2SO_4 627°C. (13·5 mole-% Li_2SO_4)
600°C. (87·5 mole-% Li_2SO_4)

LiCl-$CaCl_2$ mixtures form no compounds.

(iv) Li, Cd || Cl, SO_4[154]

The system reacts irreversibly in the direction: $2LiCl + CdSO_4 \rightarrow CdCl_2 + Li_2SO_4$; ΔH = 7·99 kg.-cal./equiv. Li_2SO_4-$CdSO_4$, $CdCl_2$-$CdSO_4$ and LiCl-Li_2SO_4 are all eutectic systems, whereas the system LiCl-$CdCl_2$ exhibits continuous solid solution with a minimum.[155] Earlier work[156] indicated the presence of compounds $3CdCl_2,4LiCl$ and $3CdCl_2,2LiCl$, but this has not been substantiated. Data for the minima are:-

LiCl-Li_2SO_4	53 mole-% Li_2SO_4	478°C.
LiCl-$CdCl_2$	77–78 mole-% $CdCl_2$	500°C.

The only stable cross-section is the diagonal joining the reaction products $CdCl_2$ and Li_2SO_4. This binary system has a monotectic three-phase region from 8–80% Li_2SO_4 at 650°C. and a eutectic at 3·5% Li_2SO_4 at 543°C. Other cross-sections are metastable with immiscible liquids forming from primary solid. The equivalent conductivity isotherm of the system LiCl-$CdCl_2$ shows marked negative deviation from linearity.[112]

(v) Li, Co || Cl, SO_4[157]

The system $2LiCl + CoSO_4 \rightleftharpoons Li_2SO_4 + CoCl_2$ has been studied by the visual polythermal method. The system LiCl-$CoCl_2$ showed a continuous series of solid solutions with a minimum at 517°C. containing 50 mole-% $CoCl_2$. The phase diagram showed a stable binary system $CoCl_2$-Li_2SO_4 with a eutectic at 548°C. containing 65 mole-% Li_2SO_4. The cross-section of the unstable LiCl-$CoSO_4$ system showed four branches, $\alpha + \beta$ LiCl, β $CoCl_2$ and $CoSO_4$.

(vi) Li, Cs || Cl, SO_4[158]

The two diagonals of the system CsCl-Li_2SO_4 and LiCl-Cs_2SO_4, are unstable. The diagonal CsCl-Li_2SO_4 intersects the crystallization fields CsCl, Li_2SO_4,Cs_2SO_4, $4Li_2SO_4,Cs_2SO_4$ and Li_2SO_4. The other diagonal intersects the fields of the two compounds and $LiCl,Cs_2SO_4$ and Li_2SO_4. The system LiCl-CsCl has a eutectic at 332°C. with 58 mole-% LiCl and a transition at 397°C. corresponding to the polymorphous transition of CsCl. Invariant ternary points:-

	Mole-%				
Temp. °C.	LiCl	CsCl	Li_2SO_4	Cs_2SO_4	Phases
Eutectic 530°	-	68	10	22	CsCl, Cs_2SO_4, Li_2SO_4,Cs_2SO_4
Eutectic 326°	53	43·5	3·5	-	LiCl, CsCl, Li_2SO_4
Transition 458°	18	52	30	-	CsCl, Li_2SO_4, Cs_2SO_4, $4Li_2SO_4,Cs_2SO_4$
Transition 450°	24·5	41·5	34	-	CsCl, Li_2SO_4, $4Li_2SO_4,Cs_2SO_4$.

(vii) Li, K || Cl, SO_4[159,160]

This is an irreversible reciprocal system with the equilibrium shifted in favour of the stable pair Li_2SO_4-KCl (6·4 kg.-cal./equiv.) The system LiCl-KCl has a eutectic at 354°C. at 41·7 mole-% KCl.[161]

(viii) Li, K || Cl, OH[162]

The equilibrium KOH + LiCl $\rightleftharpoons$ LiOH + KCl is shifted strongly towards LiOH-KCl (20·54 kg.-cal./equiv.) which is the stable diagonal. In the system LiOH-LiCl, the compound LiOH,LiCl is formed, which forms a eutectic melting at 262°C. with LiOH, containing 37 mole-% LiCl.

(ix) Li, K || Cl, NO_3[163]

(x) Li, NH_4 || Cl, NO_3[164]

Two ternary eutectics are given:-

NH_4NO_3,$LiNO_3$,NH_4Cl	84°C.
$LiNO_3$,LiCl,NH_4Cl	95°C.

(xi) Li, Na || Cl, SO_4[165]

The system is an irreversible reciprocal one with the stable diagonal NaCl-Li_2SO_4 having a eutectic at 499°C. containing 74 mole-% Li_2SO_4. The binary system LiCl-NaCl formed the incongruently melting compound LiCl, NaCl and had a eutectic at 553°C. containing 78·5 mole-% LiCl. LiCl undergoes a α–β homeomorphic transition at 565° C. and 81·5 mole-% LiCl.

(xii) Li, Pb || Cl, VO_4[166]

Eutectics:-

392°C.	79% $PbCl_2$,	13% LiCl,	8% Li_3VO_4
464°C.	64% $PbCl_2$,	21% LiCl,	15% Li_3VO_4.

(xiii) Li, Rb || Cl, F[167]

The binary systems LiF–RbF and RbF–RbCl and the main systems were studied by visual polythermal methods. The surface of the liquidus of the systems consisted of four fields of pure components.

(xiv) Li, Sr || Cl, F[168]

The system LiCl-$SrCl_2$ was studied. Neither compounds nor solid solutions are formed. The eutectic point is at 487°C. and 54 mole-% $SrCl_2$. The main system is a simple example of a completely irreversible system of the non-diagonal type.

(xv) Li, Zn || Cl, SO_4[169]

The reaction is irreversible in the direction 2LiCl + $ZnSO_4$ → Li_2SO_4 + $ZnCl_2$. The binary compound $ZnCl_2$,2LiCl (incongruent m.p. 352°C.) was found.

Invariant points (all composition expressed in mole-%):-

Eutectic 285°C.	13	LiCl	0·5 Li_2SO_4	86·5 $ZnCl_2$
Eutectic 293°C.	9	$ZnSO_4$	0·7 Li_2SO_4	90·3 $ZnCl_2$
Transition 330°C.	35·5	LiCl	2·0 Li_2SO_4	62·5 $ZnCl_2$
Transition 397°C.	28·7	$ZnSO_4$	5·0 Li_2SO_4	66·3 $ZnCl_2$.

(xvi) Li, K, Na || Cl[170]

LiCl-KCl forms no compounds; the eutectic point is at 361°C. and 58 mole-% KCl. LiCl-NaCl forms a continuous series of mixed crystals, the eutectic being 552°C. and 72 mole-% LiCl.

The main system has a eutectic at LiCl 51·5 mole-%, NaCl 11·5 mole-% and KCl 37 mole-%.

(xvii) Li, K, Rb || Cl[171]

RbCl and LiCl form a double salt LiCl,RbCl of incongruent m.p.

Five-Component Systems

(i) Li, K || Cl, SO_4, WO_4[172,173,174]

Extensive information on the phase relations in this very complex system is given.[172-174]

(ii) Li, K, Na || Cl, SO_4[175]

The cross-sections Li_2SO_4-Na_2SO_4-KCl and Li_2SO_4-Na_2SO_4-NaCl are both unstable. The presence of NaCl in the fusion of sulphates favours the appearance of $2Li_2SO_4,K_2SO_4$, but is less favourable to the transformation of Li_2SO_4,K_2SO_4; KCl favourably influences the appearance of Li_2SO_4,Na_2SO_4 and $Li_2SO_4,2Na_2SO_4$.

The quaternary transformation point is shown at 436° C. and 24% NaCl, 51% Li_2SO_4, 25% K_2SO_4.

AQUEOUS SYSTEMS CONTAINING LITHIUM CHLORIDE

(i) H_2O-LiCl-$BaCl_2$

This system is reported as forming no compounds,[176,177] but later workers[178] suggest the possibility of complex formation.

(ii) H_2O-LiCl-$BeCl_2$

The solubility isotherms have been studied at 0° C.[179] and 25° and 40° C.[176] No double salts are formed. At a composition of 17·2% LiCl and 25·8% $BeCl_2$ the solid phase is LiCl,H_2O and LiCl,$2H_2O$. At a composition 13·3% LiCl and 29·4% $BeCl_2$ the solid phase is LiCl,H_2O and $BeCl_2,4H_2O$.

(iii) H_2O-LiCl-$CaCl_2$[176,177]

No double salts are formed.

The solution has two univariant equilibria $CaCl_2,2H_2O$ and $CaCl_2,4H_2O$ at a composition of 8·25% LiCl and 39·78% $CaCl_2$, and $CaCl_2,2H_2O$ and LiCl,H_2O at 24·06% LiCl and 22·11% $CaCl_2$.

(iv) H_2O-LiCl-$CdCl_2$[176]

The system formed the compound LiCl,$CdCl_2$,2·5H_2O.

(v) H_2O-LiCl-$CoCl_2$

This system has been studied through its solubility isotherm[180] and by interfacial tension against *iso*amyl acetate.[181] The double salts $CoCl_2$, 4LiCl,$10H_2O$ and $CoCl_2$,2LiCl,$4H_2O$ were found.

(vi) H_2O-LiCl-$CuCl_2$

In this system the following solid phases separate: LiCl,H_2O, LiCl, $2H_2O$, LiCl,H_2O + LiCl,$CuCl_2$,$2H_2O$, LiCl,$CuCl_2$$2H_2O$, LiCl,$CuCl_2$,$2H_2O$ + $CuCl_2,2H_2O$ and $CuCl_2,2H_2O$.[182,183] LiCl,$CuCl_2$,$2H_2O$ forms deep red hygroscopic needles. Study of the system at low temperature[184] has resulted in the discovery of 4LiCl,$CuCl_2$,$10H_2O$. The isotherm at 0° C. shows that this salt can exist in equilibrium with LiCl,$CuCl_2$,$2H_2O$ and LiCl,$2H_2O$. The salt decomposes to LiCl,$CuCl_2$,$2H_2O$ in water. Study of the system by the interfacial tension method has indicated the formation of four complexes;[185] the interfacial tension against *n*-butyl acetate is plotted against additions of $CuCl_2$ to LiCl.

Addition of 0·025 M. $CuCl_2$ to 0·025 M. LiCl indicates that the complexes

$3LiCl,CuCl_2$, $2LiCl,CuCl_2$, $LiCl,CuCl_2$, $LiCl,2CuCl_2$ are formed.

Addition of 0·5 M. $CuCl_2$ to 0·5 M. LiCl similarly indicate the existence of $LiCl,CuCl_2$, and $LiCl,2CuCl_2$.

(vii) H_2O–LiCl–CsCl[186]

The isotherms of this system at 25°C. and 40°C. show the formation of $2CsCl,LiCl,4H_2O$.

(viii) H_2O–LiCl–$HgCl_2$[176,187]

The isotherm at 30°C. was studied. No compounds were formed. The solubility of $HgCl_2$ was increased by the presence of LiCl.

(ix) H_2O–LiCl–$MgCl_2$[188]

Isotherms at 102°, 70°, 30° and 25°C. were studied and the existence of $LiCl,MgCl_2,7H_2O$ was established.

(x) H_2O–LiCl–$MnCl_2$[189]

In addition to LiCl, $LiCl,2H_2O$, $MnCl_2,2H_2O$ and $MnCl_2,4H_2O$, the stability of the following double salts was established:-

$4LiCl,MnCl_2,10H_2O$	0–28°C.
$2LiCl,MnCl_2,\ 4H_2O$	23–76°C.
$LiCl,MnCl_2,\ 2H_2O$	Above 53°C.
$2LiCl,MnCl_2,\ 2H_2O$	Above 73°C.
$LiCl,MnCl_2,\ 5H_2O$	From below 0°C. to 26°C.

(xi) H_2O–LiCl–NH_4Cl[190]

No compounds are reported.

(xii) H_2O–LiCl–$NiCl_2$[182]

The polytherms of the system between 0° and 100°C. showed the following solid phases: $NiCl_2,2H_2O$, $NiCl_2,4H_2O$, $NiCl_2,6H_2O$, $NiCl_2,LiCl,2H_2O$, $NiCl_2,2LiCl,4H_2O$ and $NiCl_2,4LiCl,10H_2O$.

(xiii) H_2O–LiCl–$PbCl_2$

No double salts were found at 25°C.[191] or at 50°C.[192] Solubility data for the two salts are as follows:-

Concentration (g./1000 g. of water)

LiCl	$PbCl_2$		
–	10·87		
	↓ falling to		
43·77	1·39		Solid phase $PbCl_2$
	↓ rising to		
735·2	103·5		
	↓ falling slightly		
834·9	101·6	(eutectic)	Solid phase $PbCl_2$ + $LiCl,H_2O$

The $PbCl_2$ solubility then drops to zero with the second phase $LiCl,H_2O$ separating.

Isodynes of $PbCl_2$ in solutions of alkali metal chlorides were prepared. For alkali metal chlorides of the same ionic strength, the activity coefficient of $PbCl_2$ is greatest in the presence of LiCl and least in the presence of KCl.

(xiv) $H_2O-LiCl-RbCl^{186}$

The isotherms at 25°C. and 40°C. show the presence of $2LiCl,RbCl,4H_2O$ and $LiCl,3RbCl,2H_2O$.

(xv) $H_2O-LiCl-SrCl_2{}^{176,177}$

No compounds are reported.

(xvi) $H_2O-LiCl-ZnCl_2{}^{176,183}$

The following compounds are reported:-

$2LiCl,ZnCl_2,2{\cdot}5H_2O$;

$2LiCl,ZnCl_2,5H_2O$.

(xvii) $H_2O-LiCl-Li_2SO_4{}^{194}$

The solubility isotherm was studied at 25°C. The curve is composed of two branches, corresponding with the crystallization of Li_2SO_4,H_2O and $LiCl,H_2O$. There is a sharp decrease in the solubility of Li_2SO_4, which can be quantitatively precipitated by LiCl.

(xviii) $H_2O-LiCl-NaCl-KCl^{195}$

The isotherms were studied at 0–25° and 50°C. No compounds were formed. The solubilities of NaCl and KCl are markedly decreased by the presence of LiCl in the solution.

SYSTEMS CONTAINING LITHIUM CHLORIDE AND ORGANIC COMPONENTS

(i) $H_2O-LiCl-C_2H_5OH^{196,197}$

Investigation of the system down to −55°C. indicated the presence of $LiCl,3C_2H_5OH$ and $LiCl,5C_2H_5OH$. LiCl crystallized at the following temperatures and compositions:-

3·53 mole-% $LiCl,H_2O$	−9·1°C.
6·95 mole-% $LiCl,H_2O$	−23·5°C.
8·06 mole-% $LiCl,H_2O$	−30·4°C.
10·2 mole-% $LiCl,H_2O$	−47·2°C.

At 25°C., LiCl and $LiCl,H_2O$ separate, but there is no evidence of alcoholate formation.

(ii) $H_2O-LiCl-C_3H_7OH^{198}$

The liquidus contour of the system shows a pronounced lowering of temperature of initial crystallization of the solution with the addition of C_3H_7OH. At all concentrations of LiCl under 5·6 mole-% the system is a homogeneous liquid; at higher concentrations, two phases form.

(iii) $H_2O-LiCl-CH_3COOC_2H_5{}^{199}$

LiCl (molar concentration)	G. $CH_3COOC_2H_5$/100 g. water 25°C.	30°C.	35°C.	40°C.
0·1	7·64	7·36	7·08	6·81
0·2	7·48	7·17	6·85	6·54
0·3	7·23	6·91	6·58	6·25
0·4	6·99	6·67	6·34	6·02

(iv) H_2O-LiCl-$(C_2H_4)_2O_2$[200]

Saturated aqueous LiCl was prepared at room temperature, and excess dioxan was added; LiCl separated as:-

$$LiCl,H_2O,(C_2H_4)_2O_2.$$

(v) CH_3OH-LiCl-Benzoic acid[202]
C_2H_5OH-LiCl-Benzoic acid
$(CH_3)_2CO$-LiCl-Benzoic acid
$(CH_3)_2CO$-LiCl-Salicylic acid
$(CH_3)_2CO$-LiCl-Tartaric acid.

A salting out by LiCl was observed with methyl and ethyl alcohols. The solubility of the acid in acetone was increased by LiCl.

CHEMICAL PROPERTIES

In general the chemical properties of lithium chloride are straightforward and well known. Some more recently investigated aspects are outlined here.

The hydrolysis of lithium chloride has been studied between 550° and 900° C.[207] The reaction is favoured by high temperature, and good yields of hydrogen chloride are not obtained until above the melting point. The addition of silica or meta-kaolin greatly improves the yield as it reacts with the free Li_2O.

At higher temperatures (1100° C. approx.) there is evidence that hydrogen and lithium chlorides react with silica to give Li_2SiCl_6.[208]

Lithium chloride reacts readily with boric acid at 300° C. to give lithium metaborate.[209]

The reaction between lithium chloride and sodium cyanide has been studied at 570° C.[210] In the presence of iron powder as a catalyst 8·4% of Li_2CN_2 (lithium cyanimide) was formed after 30 hr.

A study of the corrosion resistance of various metals and alloys to fused lithium chloride has shown it to be most corrosive.[211] Good resistance to corrosion, even in the presence of air, is obtained with alloys of the "Hastelloy" type.

The absorbability of a number of metal ions, (e.g., $Mn^{\cdot\cdot}$, $Sc^{\cdot\cdot\cdot}$, $Fe^{\cdot\cdot\cdot}$, $Co^{\cdot\cdot}$, $Zn^{\cdot\cdot}$, $Ga^{\cdot\cdot\cdot}$ and $Au^{\cdot\cdot\cdot}$) from lithium chloride solution on anion-exchange resins has been studied.[212] Although the activity coefficients of lithium chloride and hydrochloric acid are similar, the adsorption from lithium chloride of the same concentration was very much greater.

Lithium chloride is readily absorbed on anion-exchange resins from acetone solution,[213] probably in the form of $(LiCl_2)^+$ complexes.

The exchange between lithium chloride and synthetic cation-exchange resins has also been studied.[214] The order of cations in acetone was found to be the same as in water. The percentage of cation taken by the resin was found to increase linearly with increasing acetone concentration in aqueous mixtures.

Lithium chloride is frequently used in organic reactions as a catalyst. In the catalytic cleavage of ethyl chloride into ethylene and hydrochloric acid, it is quite effective.[215] The oxidation of carbon, in the free state or combined, by potassium chlorate has been extensively studied.[216] Carbon black, (343° C.) bakelite (367° C.), and a mixture of styrene copolymers and 4:4′-di*iso*propenyldiphenyl (390° C.) all react much more vigorously with potassium chlorate in the presence of lithium chloride.

In the preparation of acetal from the reaction of acetaldehyde and ethyl alcohol, excellent results are obtained using lithium chloride as catalyst.[217]

The halolysis of the ester $(C_2H_5)_3PO_4$ by lithium chloride has been studied.[218] In water or acetic acid an ethyl group is excluded as ethyl chloride leaving $(C_2H_5)_2HPO_4$. At 200° C. the ester and lithium chloride react readily to give $(C_2H_5)_2LiPO_4$. In general[219] lithium chloride does not react with esters of phosphorous acid of the type $(RO)_3P$ at room temperature, but does so vigorously on heating to give $(RO)_2PLi$.

Lithium chloride is usually the preferred reagent for the monodebenzylation of neutral benzyl esters of the oxyacids of phosphorus,[220] e.g.:-

$$(Ph\,CH_2O)_2\,PO(OPh) \xrightarrow[\substack{LiCl\\89\%}]{\substack{100°C.\\3\text{ hr.}}} (PhCH_2O)\,PO.OH\,(OPh).$$

APPLICATIONS

Lithium chloride mixed with potassium chloride to form a eutectic mixture is the starting material for the preparation of lithium by electrolysis. On a small scale lithium has been made satisfactorily from lithium chloride by reduction with barium.[221] The reactants are heated at 850° C. in a bomb under argon; 99·5% pure lithium can be obtained by reheating the first product with lithium chloride.

Lithium chloride is frequently used to lower the operating temperature of fused electrolytic baths.

In the electrolytic preparation of titanium[222,223] $TiCl_3$ may be added to the eutectic mixture, 60 mole-% LiCl and 40 mole-% KCl. The mixture melts at 343° C. and is electrolyzed under argon or hydrogen between tungsten electrodes.

Systems of the type $KCl–LiCl–AlCl_3$ and $KCl–LiCl–MgCl_2–AlCl_3$[224] are used in the electrolytic production of aluminium. Such systems melt in the range 670–730° C. and are used for the production of the liquid metal over a wide range of concentration.

Molybdenum powder is produced in the electrolysis of K_3MoCl_6 (25 wt.-%), LiCl (34%), and KCl (41%) at 600° C.[225]

Manganese and silver are obtained by electrolysis of the following salt mixtures:-

$$AgCl–LiCl–NaCl–KCl;$$

$$MnCl_2–LiCl–NaCl–KCl.^{226}$$

A patent brazing flux[227] for titanium and zirconium and alloys containing these metals is made from the components of the system $LiF–KCl–KHF_2$. A patent melting flux[228] consists of 68% LiBr, 22% LiCl and 10% LiF, and is used for melting Mg–Li alloys, e.g., 68% Mg, 11% Li, 16% Cd, 5% Ag. A patent process is described[241] for coating steel or other ferrous materials with aluminium. A salt bath of the type KCl 38%, NaCl 28%, Na_3AlF_6 10%, AlF_3 5%, LiCl 19%, m.p. 1075°, is maintained as a layer above the molten aluminium. The article to be coated is held in the salt layer and then immersed in the molten aluminium. Lithium chloride may be used in the electrolyte of dry cells required for operation at very low temperatures.[229] An electrolyte consisting of $ZnCl_2$ 12%, LiCl 15% and NH_4Cl 8% gave 20% of the normal capacity at −40° F.

Lithium chloride is widely used in air conditioning plants.[230-236] It is considered superior to calcium chloride as it is one of the most hygroscopic of all inorganic compounds and can be used to dehumidify to 11% relative humidity at room temperature. It is non-toxic and has a high drying rate. A concentrated solution will not become entirely solid until below −60° F. The usual procedure is to recirculate foul air through a tower against a spray of lithium chloride solution, fresh air being bled in if necessary. Dust particles are readily coagulated and odours absorbed. The main lithium chloride feed is cooled and recirculated; approximately 10% is evaporated to drive off absorbed water.

In general it is thought to be cheaper to attain low humidities by the use of chemical drying agents rather than by refrigeration.[237] The limitations on drying pressures are practically eliminated by removing water vapour with a liquid absorbent. A ·1 mm. pressure can be readily maintained by lithium chloride solution.[238]

A solution consisting essentially of lithium chloride and water has been used to prevent frost formation.[242]

Titanium dioxide (anatase) can be converted to rutile by heating between 400° and 1000° C., the needed temperature depending upon the origin of the anatase. The addition of small quantities of lithium chloride lowers the transition temperature.[239]

In mullitization the most powerful mineralizing agent is lithium present as the fluoride. Lithium chloride is also very effective, 1 mole-% giving a 100% conversion at 1400° C.[240]

The exothermic heat of reaction in catalytic cracking, hydrocarbon synthesis, polymerization, etc., may be removed by decomposable hydrated salts, e.g., $LiCl,H_2O$. At the temperature of reaction the hydrate is decomposed to the chloride and steam absorbing large quantities of heat and hence acting as a moderator to the reaction. $LiCl,H_2O$ may be used between 200 and 1100° C. and may be regenerated with steam between 70 and 160° C.[243]

In the preparation of ethylene oxide from ethylene, using silver promoted with beryllium oxide as a catalyst, small additions of lithium chloride to the catalyst improve the conversion efficiency.[244]

Synthetic resin sheets may be prepared by polymerizing a layer of liquid resin on a salt solution to give a casting.[245] The optical qualities of the castings prepared using lithium chloride were very good; they were clear and free from bubbles.

A mixture of potassium chloride and lithium chloride may be used for removing fission products from uranium-bismuth fuels.[262] Rare-earth metals dissolved in liquid bismuth can be extracted nearly quantitatively in this way, while uranium remains in the metal phase.

A patent preparation[246] is described for inhibiting the build up of electrostatic charges on polythene films, fibres and coatings; it consists of an aqueous dispersion of 2% polyvinyl acetate, 0·5% lithium chloride and polymerized wood resin.

SPECTRA

In the infra-red region the addition of lithium chloride to water to give a 10 N. solution causes no change in the maximum at 1·47 μ. The entire band at 1·98 u, however, is shifted to a longer wave-length;[247] the shift is thought to be due to ion hydration.

The absorption of lithium chloride solution in the ultra-violet has been studied.[248] Values for the optical density of 3 N. solution 1 cm. thick are:-

	20° C.	40° C.	60° C.	80° C.
λ 2200 A.	0·027	0·035	0·056	0·094

A 0·5 N. solution of lithium chloride containing ammonium chloride and ammonia shows absorption in the ultra-violet.[249]

No Raman scattering other than that of water was observed with aqueous lithium chloride up to 13 N.[103] Aqueous hydrochloric acid (16·2 molal) containing lithium chloride (4–5 molal) gave a sharp Raman line at 2866 $cm.^{-1}$, indicating the presence of undissociated molecules. Some confirmation of these findings has been found using 60% lithium chloride solution.[250] A very faint band at approximately 4160 A. was found and also a possible new band at 4850 A.

The abnormal behaviour of lithium chloride in solution is again explained by its association with many water molecules.[251]

RADIATION CHEMISTRY

Measurements have been made of the angular correlation between annihilation quanta produced by positrons annihilating in lithium chloride.[252,253] Annihilation appears to occur only in the outer electrons of the negatively charged halogen ions.

Positive ion emission from lithium chloride has been studied.[254] The kinetic energy of the ions has been determined.

The scattering of copper K_α X-radiation has been determined in solutions of lithium chloride up to 13·3 moles per litre.[255] At high concentration the scattering of water is repressed. The data are incompatible with the assumption that there is a random distribution of ions in the solution, but indicates ions in a distorted water lattice. At high concentrations the whole structure is thought to become similar to a solid salt containing water.

Negative ions from a discharge in lithium chloride vapour may be drawn off and accelerated by a potential difference. A beam, thought to be $LiCl_2^-$, impinges on a metal target; this results in the liberation of positive ions.[256]

A target of lithium chloride bombarded with deuterons of energies up to 900,000 e.V. has given yields several hundred times as great as by bombarding beryllium with helium. At the maximum deuteron current of 30 microamps about 100 recoil particles per minute were obtained. This is about 100 times the intensity obtained by means of the strongest polonium α-particle sources.[257]

ANALYTICAL ASPECTS OF LITHIUM CHLORIDE CHEMISTRY

The effect of neutral salts on the indicator acidity function H_0 has been measured by spectrophotometric means in 0·01, 0·1 and 1 M. hydrochloric acid solutions, with the simple basic indicators 2:4-dichloroaniline, p-nitroaniline, diphenylamine and *o*-nitroaniline. In 0·01 and 0·1 M. acid the salt concentration effect is linear up to salt concentrations of 4 M., and is specific for the salt. The apparent acidity is increased by salts in the order:-

$$LiCl > NaCl > KCl.$$

The apparent acidity is decreased by tetramethylammonium and tetraethylammonium bromides.[258]

Lithium chloride has been potentiometrically and visually titrated in glacial acetic acid solution against 0·1 N. mercuric, lead and thallous acetates. The indicators used were potassium nitroprusside or dithizone for mercury, neutral red or thionine for thallium and neutral red, thionine or safranine for lead.[259]

A calomel electrode involving a half-cell of mercury, a mercury-mercurous chloride paste and ethylenediamine saturated with mercurous chloride and lithium chloride, is used in titrations of weak acids and bases in water-free solvents.[260]

The polarographic reductions of lead in methyl or ethyl alcohol and cadmium in methyl alcohol, ethyl alcohol or acetic acid were studied with lithium chloride as supporting electrolyte.[261] Acetyl chloride, propionyl chloride, butyryl chloride, *iso*valeryl chloride, benzoyl chloride, β-phenylpropionyl chloride, acetyl bromide, propionyl bromide and benzoyl bromide gave well-defined waves in acetone saturated with lithium chloride at 30° C.

A calomel electrode made with lithium chloride instead of potassium chloride and acetone instead of water was found to be satisfactory.

SECTION XII

LITHIUM BROMIDE

By W. P. DOYLE

Preparation

A suggested method of manufacture consists in treating di-lithium sodium orthophosphate, Li_2NaPO_4, with aluminium bromide or ferric bromide to precipitate the phosphate of aluminium or iron and form lithium bromide.[1] The manufacture of lithium bromide has been described in detail.[2]

Physical Properties

X-Ray diffraction studies of aqueous lithium bromide solutions show a broad ring, the position of which is independent of concentration; the ring is ascribed mainly to interference between the scattering from the bromide ion and that of the surrounding water molecules.[3]

An investigation of the anode-ray emission of lithium bromide confirmed the lithium line at 2934·1 A. previously observed and established a general correspondence with the helium spectrum.[4] The frequency of the lattice oscillations of lithium bromide has been calculated, on the basis of the Born model, to be $6{\cdot}7 \times 10^{12}$; the anharmonicity was also calculated.[5] Oriented overgrowths of lithium bromide on a potassium chloride substrate have been considered in their relation to lattice stability.[6] The electrical conductivity of solid silver bromide with added lithium bromide has been measured[7] from 200°–400° C.; the results are shown in Fig. 1, where the ordinate gives the conductivity relative to that of pure silver bromide at the same temperature and where, to avoid confusion, for each 25° C. difference in temperature the curves are displaced 0·1 of an ordinate unit relative to one another; the results show that the added lithium bromide forms a normal substitution lattice.[7] Values calculated theoretically for the lattice constant, energy content, compressibility and infra-red frequency of lithium bromide agree fairly well with observed values.[8] From a consideration of the relations between the lattice energies, melting points and boiling points of the alkali halides, it is suggested that lithium halides are more covalent than the other alkali halides.[9] The formation of lithium bromide is accompanied by the emission of ultraviolet radiation.[10] The dielectric constant of lithium bromide is 10·95.[11]

The molecular magnetic susceptibility of lithium bromide in aqueous solution is[12] $-36{\cdot}0 \times 10^{-6}$; this value has been confirmed.[13] The molecular magnetic susceptibility of solid lithium bromide is[13] $-34{\cdot}7 \times 10^{-6}$.

The magneto-optical rotation for Na D lines of aqueous solutions of lithium bromide has been measured.[14] The development of turbidity on cooling or heating mixed crystals of lithium and sodium bromides has been investigated and the results are given in Table I.[15]

The cubic compressibility of solid lithium bromide is reported as[16] $5{\cdot}0 \times 10^{-6}$ per megabar and as $4{\cdot}31 \times 10^{-12}$ reciprocal dynes per sq. cm. at 30° C.;[17] from the latter value the cubic compressibility at absolute zero is, by extrapolation, $3{\cdot}2 \times 10^{-12}$ reciprocal dynes per sq. cm.;[17] the change of compressibility with pressure is $24{\cdot}5 \times 10^{-12}$ reciprocal dynes per sq. cm. and is

Refs. p. 228

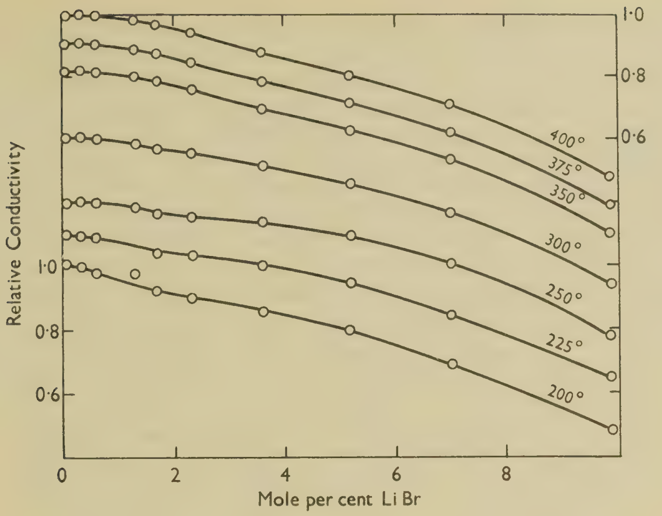

FIG. 1. CONDUCTIVITY OF LiBr–AgBr MIXED CRYSTALS

independent of temperature between 30° and 75° C.; the average change of compressibility with temperature is $8{\cdot}4 \times 10^{-4}$ reciprocal degrees centigrade between 30° and 75° C.[17] These experimental results have been discussed in relation to lattice theory.[16,17]

TABLE I.- TURBIDITY OF LITHIUM BROMIDE–SODIUM BROMIDE CRYSTALS

Mole fraction of NaBr	On cooling, development of turbidity		On heating, disappearance of turbidity	
	begins at (°C.)	ends at (°C.)	begins at (°C.)	ends at (°C.)

The refractive indices of molten silver bromide–lithium bromide solutions were measured as a function of temperature and concentration; the molar refractivity of the solutions was found to be an additive function of the mole fraction.[20]

The heat of sublimation of lithium bromide was calculated[21] to be between 15 and 35 kg.-cal. per mole using a previously developed equation[22] relating thermochemical properties to lattice structure. The heat of dissociation of lithium bromide vapour, determined by an optical method,[23] is 96·7 ± 1·4 g.-cal.[24] as compared with the thermochemical value 87·06 g.-cal. It is suggested that the optical method is not completely valid.[24]

The changes in free energy of molten silver bromide on dilution with lithium bromide have been determined;[18] the results, which are given in Table IV, have been discussed on the basis of simple assumptions as to ionization.

TABLE IV.- CHANGE IN FREE ENERGY (in g.-cal.) OF SILVER BROMIDE ON DILUTION WITH LITHIUM BROMIDE

130	0·9619	-	0·8967

In aqueous solution, the heats of solution and dilution of lithium bromide from extreme dilution up to saturation were determined at 25°C.;[27] the integral heat of dilution, the heat effect caused by the dilution of a solution containing 1 mole of salt from a particular initial concentration to infinite dilution, was determined and the results discussed in relation to the nature of solutions of strong electrolytes.[28,29] The concentration dependence of the heat of dilution for aqueous lithium bromide solutions agrees with that calculated on the basis of a modified Debye-Hückel theory.[30] The molar heat of solution of lithium bromide in liquid ammonia is[31] 19·715 kg.-cal. The apparent molal heat capacity, and hence the partial molal heat capacity, of lithium bromide in aqueous solution have been related to the concentration of the solution;[30-32] this correlation has been discussed in relation to the hydration of ions.[25] The concentration dependence of the apparent molar heat capacity of aqueous lithium bromide solution agrees with that calculated by means of a modification of the Debye-Hückel theory.[30]

The sum of the standard free energies of hydration of lithium and bromide ions was, from standard electrode potential and other data, calculated as 184·9 kg.-cal. per mole.[33] The total heat of hydration of lithium bromide has, from measurements of heat of solution and the value of the lattice energy, been critically selected as 194 kg.-cal. per mole; this value was used to obtain the heat of hydration of the simple lithium ion, Li^+, 121 kg.-cal. per g.-ion, and of the simple bromide ion, Br^-, 72 kg.-cal. per g.-ion; the results are discussed in relation to the nature of the hydration sphere.[34] The limit of full solvation was measured and discussed in relation to the structure of concentrated solutions of lithium bromide.[35] Information about the ions in a concentrated solution of lithium bromide has been derived from vapour pressure data.[36]

Three hydrates of lithium bromide have been observed[37] – the monohydrate, dihydrate and trihydrate. In a later investigation, a pentahydrate, stable below −49° C., was found.[38]

The solubilities of lithium bromide in methanol, acetonitrile and formic acid have been determined[39] at 18° and 25° C.; the results are given in Table VI.

TABLE VI.- SOLUBILITY (*S*) OF LITHIUM BROMIDE IN METHANOL, ACETONITRILE AND FORMIC ACID

Formic acid	18	82
	25	80

The solubilities of lithium bromide in diacetone alcohol and in mesityl oxide have been determined[40] from 20° to 65° C.; the results are given in Table VII, where the solubility is the weight of anhydrous salt dissolved in one gram of solvent in the presence of the solid phase indicated.

TABLE VII.- SOLUBILITY OF LITHIUM BROMIDE IN DIACETONE ALCOHOL AND MESITYL OXIDE

65·0	0·2916	0·4550

A number of phase equilibrium studies of systems containing lithium bromide have been made. The following double compounds have been detected: (*a*) $LiBr,2LiOH$ in the system $LiBr–LiOH–KBr–LiOH$;[41] (*b*) $CoBr_2,LiBr$, and possibly $CoBr_2,2LiBr$, in the system $CoBr_2–LiBr–H_2O$–2-butanone;[42] (*c*) $LiBr,4CH_3OH$ in the system $LiBr–CH_3OH$;[43] (*d*) $LiBr,4C_2H_5OH$ in the system $LiBr–C_2H_5OH$;[44] (*e*) $LiBr,4n\text{-}C_3H_7OH$ in the system $LiBr–n\text{-}C_3H_7OH$;[43] (*f*) $LiBr,2(CH_3)_2CO$ in the system $LiBr–(CH_3)_2CO$.[45] In the system $AgBr–LiBr$ solid solutions are formed.[46] Analysis of the anhydrous system $LiBr–MgBr_2$ shows the presence of two series of mixed crystals, one being richer in magnesium bromide, the other in lithium bromide.[47] The system $MgBr_2–LiBr–H_2O$ forms no compounds and the phase diagram shows a rather short $MgBr_2,6H_2O$

branch followed by a branch of solid solutions;[48] a later investigation of the same system confirmed that no double salts are formed but di-, tri- and penta-hydrates of lithium bromide and hexa- and deca-hydrates of magnesium bromide were found.[38] In the system $CaBr_2$–LiBr–H_2O there is a series of solid solutions, and in the $BaBr_2$–LiBr–H_2O system lithium bromide acts as a salting-out agent towards barium bromide.[49] In the system LiBr–H_2O–C_2H_5OH no alcoholates were detected and the solid phases recognized were anhydrous lithium bromide and the mono- and di-hydrate of lithium bromide.[50] Other systems that have been investigated are LiBr–RbBr[51] and $HgBr_2$–LiBr–H_2O.[52] A study of the precipitation of silver bromide in the presence of lithium bromide showed that in normal analytical practice there is no contamination of the precipitate by the formation of a solid solution.[53]

The densities at 35°C. of concentrated aqueous solutions of lithium bromide have been determined[54] and are given in Table VIII.

TABLE VIII.- DENSITY OF AQUEOUS LITHIUM BROMIDE SOLUTIONS

Density at 35°C., g./c.c.	1·13859	1·31036	1·37671	1·44911

The density of an aqueous solution containing 39·4% of lithium bromide has been measured[55] from –70° to 20°C. and the results are given in Fig. 2.

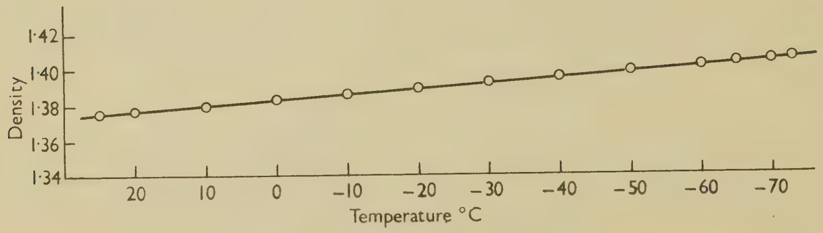

FIG. 2. DENSITY OF AQUEOUS SOLUTION CONTAINING 39·4% OF LITHIUM BROMIDE

For aqueous solutions of lithium bromide the thermal expansion between 20° and 40°C. and the specific volume at 25°C. have been determined;[56] representative thermal expansion data are given in Table IX, where $\Delta_t v$ is the change in specific volume resulting from a temperature change from 25·00°C. to the temperature indicated; specific volumes are given in Table X. From the data, the apparent volume expansion and expansibility were computed; there was no evidence of breaks in the curves of the apparent expansion plotted against the concentration between 20° and 35°C.[56]

For methanol solutions and for glycol solutions of lithium bromide, the thermal expansion and the specific volume at 25°C. have been determined.[57] $\Delta_t v$, the finite change in specific volume for a given rise of temperature, was expressed as a quadratic function of the temperature by the equation:-

$$\Delta_t v = A + B\,(t - 25) + C\,(t - 25)^2.$$

The coefficients of the equation for methanol solutions of lithium bromide are given in Table XI and those for glycol solutions are given in Table XII.

Table XIII gives the specific volumes at 25°C. for methanol solutions and for glycol solutions of lithium bromide. The apparent molal expansibility is negative and increases with concentration; comparison of the data with those for aqueous solutions indicate that structural changes in water largely determine the expansion of aqueous solutions.[57]

The diffusion coefficients of aqueous solutions of lithium bromide have been measured;[58] the results are given in Table XIV where D_F is the diffusion coefficient calculated from Fick's equation and D_B that calculated from the Boltzmann equation.

Excellent agreement was obtained between the experimental results and those calculated on the basis of the Nernst–Planck theory of diffusion in electrolytes modified by using, as an approximation, Bjerrum's concept of association; this agreement permits the calculation of association as a function of concentration.[58]

The relative viscosity of an aqueous solution containing 39·4% of lithium bromide has been measured[55] from −70° to 20°C. and the results are shown in Fig. 3.

The theory of the viscosity of electrolyte solutions has been extended by introducing the concept of closest approach, but comparison of the values calculated for lithium bromide and other uni-univalent electrolytes with the experimental values shows that this treatment gives no improvement on the older theory.[59] The compressibility coefficients of concentrated aqueous solutions of lithium bromide have been measured[54] and are given in Table XV; on the basis of the measurements the irregular properties of concentrated solutions of lithium bromide have been discussed.

The concentration dependence of the compressibility of aqueous solutions of lithium bromide, calculated using a modified Debye-Hückel theory, agrees with experimental data.[30] The compressions, to 1000 bars, of solutions of

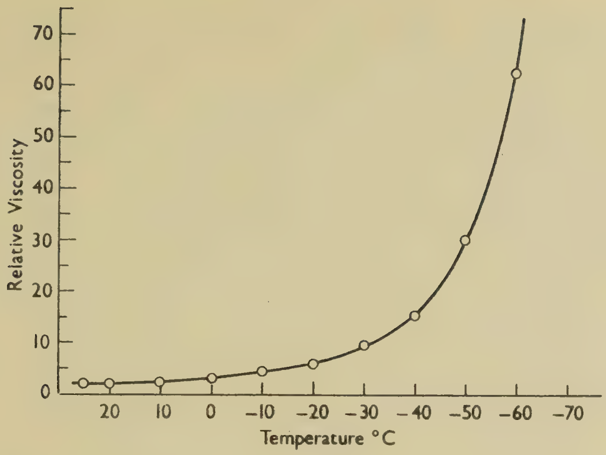

FIG. 3. RELATIVE VISCOSITY OF AQUEOUS SOLUTION CONTAINING 39·4% OF LITHIUM BROMIDE

lithium bromide in methanol and in glycol were measured and apparent volumes, compressions and effective pressures were calculated.[60]

TABLE XV.- COMPRESSIBILITY COEFFICIENT (β) OF AQUEOUS LITHIUM BROMIDE SOLUTIONS

Wt.-% of LiBr	18·076	34·706	39·999	45·183
$\beta \times 10^6$	35·28	30·11	28·63	27·12

The vapour pressure of aqueous solutions, containing from 50 to 68% of lithium bromide, has been expressed mathematically as a function of the absolute temperature.[61] Cryoscopic measurements of very dilute solutions of lithium bromide in *cyclo*hexanol gave results in complete agreement with those derived from the osmotic theory of Debye and Hückel.[62] Cryoscopic investigation of the complex $LiBr,2AlBr_3$ in benzene showed that the complex is very much associated and that the degree of association increases with concentration; addition of lithium bromide to a benzene solution of aluminium bromide raises the freezing point, thus indicating a further association of aluminium bromide during the formation of complex compounds.[63] The molalities of isopiestic solutions at 25°C. for $LiBr–CaCl_2$ and $LiBr–H_2SO_4$ have been reported and used to calculate the osmotic coefficient for lithium bromide.[64] The freezing points of aqueous solutions of lithium bromide were measured.[65]

The decomposition potential of fused lithium bromide is 2·95V. and this experimental value agrees with those calculated by two different methods.[66] The decomposition potentials of a mixture of lithium bromide and aluminium bromide (equimolar amounts) in toluene is 3·5V., in xylene 3·4V., in ethyl bromide 3·6V., in ethylene dibromide 3·6V., in nitromethane 3·8–4·0V. and in nitrobenzene 5·1V.; for a mixture containing 2 moles of aluminium bromide for each mole of lithium bromide the decomposition potentials are 2·3V. in benzene, 2·6V. in toluene, 2·9V. in xylene, 2·0V. in ethyl bromide, 2·0V. in ethylene dibromide, 2·0V. in nitromethane and 4·4V. in nitrobenzene.[67]

The conductivity of an aqueous solution containing 39·4% of lithium bromide has been measured[55] from −70° to 20°C. and the results are shown in Fig. 4.

The theory of the conductivity of aqueous solutions of electrolytes has been extended by introducing the concept of closest approach; complete

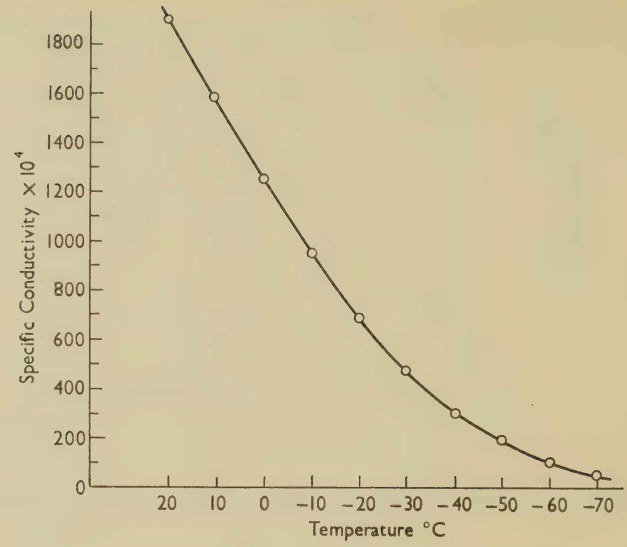

FIG. 4. CONDUCTIVITY OF AN AQUEOUS SOLUTION CONTAINING 39·4% OF LITHIUM BROMIDE

quantitative agreement of the calculated values with experiment is found for lithium bromide and other uni-univalent electrolytes at concentrations less than 0·1N.[59] Lithium bromide is completely dissociated in moderately concentrated aqueous solutions.[30] The field effect in lithium bromide was measured by investigating the variation of conductivity with electric field strength up to 100 kV./cm.; at 100 kV./cm., the percentage increase in conductivity at low field conductivities is 7·3 ohm^{-1}cm.$^{-1}$ [68] For aqueous lithium bromide solutions, the experimental variation of conductivity with concentration, shown in Fig. 5, does not agree with the Debye–Onsager equation; correspondingly the voltage effect is relatively large.[69] The effect of lithium bromide, and of other uni-univalent electrolytes, on the concentration ionization constant of acetic acid in aqueous solutions of ionic strengths 1·0 and 2·7 was determined at 25°C.; it was found that the value of p*K* for acetic acid is an additive quantity dependent separately on each ionic species of the added electrolyte; the Brønsted specific ionic interaction theory fully explains the observed additivity.[70]

Solutions of lithium bromide in molten iodine bromide are poor conductors.[71]

The conductivity of lithium bromide in organic solvents has been fairly widely studied. In acetone, conductivity measurements, given in Table XVI, have shown that lithium bromide shows behaviour intermediate between that to be expected for a high degree of dissociation and that for extensive molecular association.[72]

TABLE XVI.- EQUIVALENT CONDUCTIVITY (Λ) OF LITHIUM BROMIDE IN ACETONE

(c = g.-equiv. per litre)

10^4c	0·7663	1·148	1·525	2·057	5·096	7·561	8·025	24·11	33·23
Λ	138·0	132·7	128·0	121·2	100·0	91·52	88·70	62·39	55·51

The dissociation constant of lithium bromide in aqueous acetone was calculated from the conductances of a series of lithium bromide solutions in acetone–water mixtures measured at 25° and 35°C.[73] The dissociation constant of lithium bromide[74] in 90% acetone–10% water is $12{\cdot}0 \times 10^{-3}$. In anhydrous acetic acid solution, the limiting equivalent conductance of lithium bromide is 29 cm.^{2}equiv.$^{-1}$ohm^{-1} and the ion-pair dissociation constant is $7{\cdot}2 \times 10^{-7}$ as determined by conductivity measurements; these and similar data for other substances were used to test the hypothesis that exchange reactions of the type $MBr + M'X \rightleftharpoons M'Br + MX$ (where M = Li, Na or K and $M'X$ = sodium acetate, sodium formate, lithium acetate or lithium formate) occur in acetic acid.[75] To a mixture of lithium bromide and dioxan contained in a conductivity cell, water or ethyl alcohol was added gradually in measured amounts and the volume at which a sharp rise in current occurred was determined; the critical quantities are for water, 2·69 moles per litre of dioxan and for alcohol, 6·36 moles per litre of dioxan; the results are discussed in relation to the mechanism of dissociation of electrolytes.[76] The measured conductivities of solutions of lithium bromide in benzonitrile have been interpreted as showing that, except in extremely dilute solution, lithium bromide is incompletely dissociated.[77] From the measured conductivities in benzonitrile and the dielectric constant of the solvent, the dissociation constant of lithium bromide is calculated to be $3{\cdot}1 \times 10^{-2}$ at 25°C.[78] The measured conductivities of dilute solutions of lithium bromide in benzaldehyde are consistent with the square-root rule of Kohlrausch deduced theoretically by Debye and Hückel as a limiting law for dilute solutions.[79] The dissociation constant of lithium bromide in acetophenone is $0{\cdot}92 \times 10^{-4}$ from conductivity measurements.[80] The measured equivalent conductivities of solutions of lithium bromide in *cyclo*hexanol are not in agreement with the Debye–Hückel–Onsager theory of conductivity in solutions of low dielectric constant.[81] The limiting conductivity, extrapolated from measured conductivities, of lithium bromide in ethyl cyanoacetate is 19·10 and of lithium bromide in *o*-toluonitrile is 27·80; the conductivity of the solutions is a linear function of the square-root of the concentration.[82] The conductivity of solutions of lithium bromide in acetone

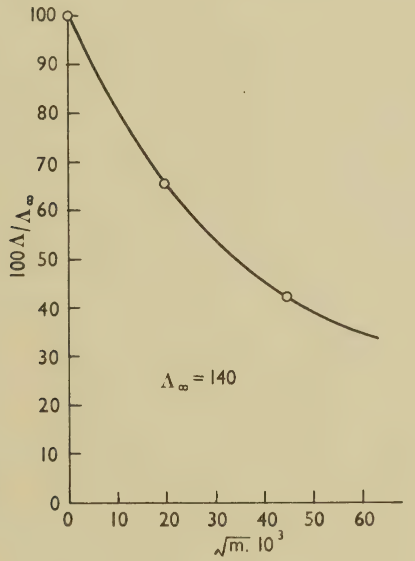

FIG. 5. EQUIVALENT CONDUCTIVITY (Λ) OF AQUEOUS LITHIUM BROMIDE
(m = moles per litre)

have been measured with 75-cm. waves; the increase of conductivity with frequency is of an order of magnitude agreeing with the Debye–Falkenhagen theory.[83]

The electrochemistry of mixtures of lithium and aluminium bromides in organic solvents has been investigated;[63,84,85] in ethyl bromide, ethylene bromide, benzene and toluene, the specific conductivity increases with increase in the concentration of lithium bromide; the maximum specific conductivity in ethyl bromide is 12·78 × 10^{-3}, in benzene 5·72 × 10^{-3} and in toluene 5·28 × 10^{-3} reciprocal ohms and that in ethylene bromide has also been measured. Electrolysis of lithium bromide–aluminium bromide mixtures in ethyl bromide, benzene, toluene or xylene produces metallic aluminium at the cathode; but if the electrolysis is carried out in nitrobenzene, metallic lithium is deposited. The decomposition potential in ethyl bromide is 2v., in benzene 1·60v., and in toluene 2·00v.

The electrolytic transport of water in 0·1N-lithium bromide solution is 8·15 and the transport number of the lithium ion[86] is 0·401. The transport number of bromide ion in an acetone solution of lithium bromide is 0·833; addition of methanol to the solution causes a sharp decrease in the transport number of bromide ion and hence it is concluded that in acetone lithium bromide forms complexes which are destroyed by methanol.[87]

For lithium bromide the Soret coefficient[88] (× 10^4) is –20; other measurements have shown that the coefficient is temperature dependent and that it can be obtained by the summation of the coefficients of the single ions.[89]

The activity coefficients of lithium bromide at 25°C. have been calculated[64] from the molalities of isopiestic solutions of lithium bromide and calcium chloride and from the molalities of isopiestic solutions of lithium bromide and sulphuric acid; the results are given in Table XVII.

The concentration-dependence of the activity coefficient of aqueous lithium bromide solutions was calculated using a modified Debye–Hückel theory and found to agree with experimental data.[30] In lithium bromide solutions, the ionic activity coefficient of water, calculated from e.m.f. measurements, varied between 0·999 and 0·942 in the concentrations studied and is slightly lower than in lithium chloride solutions.[90] The measured activity coefficient of ethyl acetate in aqueous lithium bromide solution is in fairly good semi-quantitative agreement with that calculated using a modified Debye–McAulay-type equation and that calculated using the Debye equation.[91]

Lithium bromide increases the rate of hydrolysis of benzoyl chloride in aqueous acetone at 25°C.;[92] for approximately 0·03N-lithium bromide, the rate increase in 5% water – 95% acetone is 175%, that in 10% water – 90% acetone is 40% and that in 15% water – 85% acetone is 15%; in 15% water –

85% acetone, the rate increase for 0·013N-lithium bromide is 8·3 and that for 0·045N-lithium bromide is 18%. Lithium bromide increases the rate of hydrolysis of *tert.*-butyl bromide in 10% water - 90% acetone at 25°C.;[74] the effect on k°, the rate constant at zero ionic strength, is given in Table XVIII.

TABLE XVIII.- EFFECT OF LITHIUM BROMIDE ON RATE OF HYDROLYSIS OF *tert.*-BUTYL BROMIDE AT 25°C.

Molarity of LiBr	0·000	0·024	0·046	0·106
$10^5 k^\circ$	1·25 ± 0·02	1·36 ± 0·03	1·42 ± 0·04	approx. 25

Lithium bromide in acetone has been used in a demonstration of bimolecular anionotropic change.[93]

The adsorption by precipitated lead sulphide of lithium bromide from solutions saturated with lead sulphide and lead sulphate has been studied and discussed in relation to the compatibility of the space lattices.[94] The coagulation concentration of lithium bromide for sulphur sols was measured and discussed.[95] Electrophoresis was studied in solutions of poly-4-vinyl-N-butylpyridinium bromide with added lithium bromide.[96] An appreciable Donnan membrane effect found with solutions of polymethacrylic acid in ethanol is eliminated by addition of lithium bromide.[97]

Chemical Properties

Lithium bromide does not react with dry air at 560°C.; it is not hydrolysed at its melting point (547°C.) but at about 560°C. it reacts with a mixture of steam and oxygen to give bromine.[98] Lithium bromide accelerates the reaction of solid potassium chlorate with graphite and with Nuchar and causes mixtures of potassium chlorate and charcoal black to ignite at 343°C.[99] Electrolysis of lithium bromide in anhydrous acetic acid using a silver anode results in the formation of silver bromide in quantitative yield.[100] The compound CCl_3SO_2Cl rapidly liberates bromine from lithium bromide in acetone; triphenyl methyl chloride, Ph_3CCl, has no action on lithium bromide in acetone.[101] The action of lithium bromide on esters of phosphorous acid has been studied; with esters of the general formula $(RO)_3P$, the products are RBr and $(RO)_2POLi$; with the dibutyl ester of phosphorous acid, $(BuO)_2POH$, the products are butyl bromide and a compound of formula $C_8H_{18}O_3PLi$; with the diethyl ester of phosphorous acid, $(EtO)_2POH$, an unidentified compound is formed which contains halogen and 18·2–18·6% of phosphorus.[102] The presence of lithium bromide markedly increased the thermal instability of amylsodium and, alone among the alkali halides, resulted in the formation of diamyl alcohol, triamyl–carbinol and a hexadecene as decomposition products.[103] Reaction of the 1:2 addition compound of tetraphenyl lithium borohydride, $Li(BPh_4)$, and lithium bromide, $Li(BPh_4),2LiBr$, with mercury in chloroform yields some phenyl mercuric chloride.[104]

The existence of the complex tetrabromo-cobalt (II) ion, $[CoBr_4]^{-2}$, in butyl alcohol solutions of cobalt (II) perchlorate and lithium bromide has been shown spectrophotometrically.[105] Spectrophotometric measurements have also shown that, in ethanol solution, bromide ion, added as lithium bromide, displaces chloride ion from the complex tetrachloro-cobalt (II) ion, $[CoCl_4]^{-2}$, more readily than does iodide ion, added as lithium iodide.[106]

The 1:2:2 addition compound of lithium bromide, aluminium bromide and nitrobenzene, $LiBr,2AlBr_3,2PhNO_2$, has been prepared and its properties examined.[107] β-Alanine, $H_2NCH_2CH_2CO_2H$, gives with lithium bromide the addition compound $H_2NCH_2CH_2CO_2H,LiBr,1\ 5H_2O$.[108]

Dehydrobromination of the 4-Br derivative of 17α-hydroxy-21-acetoxypregnane-3,11,20-trione has been accomplished by using lithium bromide (*a*) in formylpiperidine and (*b*) in dimethylacetamide.[109] Methyl triphenyl phosphonium bromide, Ph_3PMeBr, in ether with phenyl lithium, PhLi, under nitrogen gave triphenylphosphine methylene, $Ph_3P{:}CH_2$, which was kept in solution and treated with benzophenone in ether giving[110] a lithium bromide adduct of the compound $Ph_3P^+ \rightarrow O^-$. The kinetics of the exchange of radioactive bromide ion (from radioactive lithium bromide) with substituted phenyl and benzyl bromides have been studied.[111] The isotopic exchange reactions between radioactive lithium bromide and *iso*propyl bromide and *tert.*-butyl bromide in anhydrous acetone have also been studied.[112]

Applications

Aqueous solutions of lithium bromide can be used in air conditioning,[113] in the dehydration of moist acid-containing gases[114] and in the dehydration of mineral oil.[115] Fused lithium bromide can be used in a flux for melting magnesium-lithium alloys[116] and in the electrolyte for a primary cell.[117] The effect of lithium bromide on cellulose dispergation has been studied.[118]

Analytical

In connection with the analytical control of pharmaceutical materials it was shown that 50 parts of sulphate in 100,000 parts of lithium bromide could be detected turbidimetrically.[119]

SECTION XIII

LITHIUM IODIDE

By W. P. DOYLE

Preparation

Lithium iodide has been prepared by the action of iodine on lithium hydride in ether solution; the method is rapid, practically quantitative, yields a pure product and is almost certainly suitable for other metallic iodides of groups I and II.[1] A similar method, having the same advantages but actually applied only to barium iodide, depends on the reaction of the metallic hydride with ammonium iodide in pyridine.[1] To ensure the stability of lithium iodide, it is recommended[2] that, after preparation, the salt be fused in a quartz vessel at 245–63° C.

Physical Properties

The crystal structure of lithium iodide has been determined;[3] it possesses the rock-salt structure and the interatomic distance is 3·03 A. A later *X*-ray powder analysis confirms[4] the rock-salt structure but gives the interatomic distance as 3·537 A. The discrepancy between the two determinations has been discussed and it is suggested that the material used in the later determination was probably not anhydrous.[5] The crystal structure of lithium iodide trihydrate, $LiI,3H_2O$, has been determined[6] and confirmed.[7] The unit cell is hexagonal and contains two molecules. The spacings are: $d_{110} = 7{\cdot}45$ A.; $d_{001} = 5{\cdot}45$ A. The space group is *6e* – 4. *X*-Ray diffraction studies of aqueous lithium iodide solutions show a broad ring, the position of which is independent of concentration; the ring is ascribed mainly to interference between the scattering from the iodide ion and that of the surrounding water molecules.[8]

The lattice energy of lithium iodide is, from mass spectral studies, 174·0 kg.-cal. per mole.[9] An investigation of the anode ray emission of lithium iodide confirmed the lithium line at 2934·1 A. previously observed and established a general correspondence with the helium spectrum.[10] The frequency of the lattice oscillations of lithium iodide has been calculated, on the basis of the Born model, to be $6{\cdot}7 \times 10^{12}$; the unharmonicity was also calculated.[11] The density effect for the ionization losses of charged particles was calculated using a dispersion model.[12] The dielectric constant, determined experimentally,[13] is 8·2 and the value calculated theoretically is in good agreement with lattice energy data.[14] The photoelectric effect of a solution of lithium iodide, measured by a spark counter, is large and is linearly related to the concentration of the solution.[15]

The cubic compressibility of lithium iodide has been reported[16] as 7·2 per megabar × 10^{-6}. Later compressibility measurements,[17] over the pressure range 12000 kg.cm.$^{-2}$, showed that at 30°C. the cubic compressibility of anhydrous lithium iodide is represented by the equation:

$$-\Delta V/V_0 = 58{\cdot}89 \times 10^{-7}\, p - 107{\cdot}4 \times 10^{-12}\, p^2,$$

and that of the trihydrate, assuming equal compressibility in all directions, by the equation:

$$-\Delta V/V_0 = 65{\cdot}1 \times 10^{-7}\, p - 117 \times 10^{-12}\, p^2.$$

The compressibility calculated on the basis of the theory of the grating[18] is qualitatively consistent with the experimental data.[16] For aqueous solutions of lithium iodide of various concentrations, compressibilities up to 1000 bars have been determined[19] at 25°C. and are given in Table I where x_1 is the weight fraction of water in the solution, x_2 is the weight fraction of lithium iodide in the solution and $-\Delta pv$ is the specific compression of a solution for an increase of pressure from 1 to 1000 bars.

TABLE I.- COMPRESSIBILITY OF AQUEOUS SOLUTIONS OF LITHIUM IODIDE

$100\ x_2$	0·00	9·62	25·58	33·87	46·37	53·33
$-\Delta pv/x_1 \times 10^4$	394·6	386·9	375·7	370·2	363·8	362·5

The heat of sublimation of lithium iodide is calculated[20] as between 15 and 35 using a previously developed equation[21] relating thermochemical properties to lattice structure. The partial heats of sublimation to monomer and dimer at 0° abs. are 44·9 and 45·5 kg.-cal. per mole respectively, as determined from mass spectral measurements.[9] The heat of dissociation of dimeric vapour, $(LiI)_2$, into monomeric vapour, LiI, is 44·4 kg.-cal. per mole;[9] the heat of dissociation of the monomeric vapour is 78·8 kg.-cal. per mole as determined from electron impact appearance potentials, and 88·0 kg.-cal. per mole, as determined from optical studies.[9]

The sum of the standard free energies of hydration of lithium and iodide ions was, from standard electrode potential and other data, calculated as 177·9 kg.-cal. per mole.[22] The total heat of hydration of lithium iodide has, from measurements of heat of solution and the value of the lattice energy, been critically selected as 184 kg.-cal. per mole; this value was used to obtain the heat of hydration of the simple lithium ion, Li^+, 121 kg.-cal. per g. ion, and of the simple iodide ion, I^-, 63 kg.-cal. per g. ion; the results are discussed in relation to the nature of the hydration sphere.[23] The heat of hydration of anhydrous lithium iodide to the hemi-hydrate ($LiI \rightarrow LiI,0{\cdot}5H_2O$) is 10·1 kg.-cal., of the hemi-hydrate to the monohydrate ($LiI,0{\cdot}5H_2O \rightarrow LiI,H_2O$) 9·3 kg.-cal., of the monohydrate to the dihydrate ($LiI,H_2O \rightarrow LiI,2H_2O$) 16·4 kg.-cal., and of the dihydrate to the trihydrate ($LiI,2H_2O \rightarrow LiI,3H_2O$) 16·0 kg.-cal. per mole.[24] The limit of full solvation has been measured and discussed in relation to the structure of concentrated solutions of lithium iodide.[25] Information about the hydration of the ions in a concentrated solution of lithium iodide has been derived from vapour pressure data.[26]

The apparent molal heat capacity, and hence the partial molal heat capacity, of lithium iodide in aqueous solution have been related to the concentration of the solution.[27]

Four hydrates of lithium iodide have been observed, $LiI,0{\cdot}5H_2O$, LiI,H_2O, $LiI,2H_2O$ and $LiI,3H_2O$; the congruent melting point of the monohydrate is 131°C. or higher, that of the dihydrate is 79°C. and that of the trihydrate is[24] 75°C. The solubility of lithium iodide in nitrobenzene is 5·27 ± 0·04% at 250°C.; the distribution ratio of lithium iodide between water and nitrobenzene varies from 3250 to >6830 as the concentration of lithium iodide in the water layer decreases from 42·2 to 10·1 g. of lithium iodide per 100 g. of solution.[28] The solubilities of lithium iodide in methanol, acetonitrile and formic acid have been determined at 18° and 25°C.; the results are given in Table II.[29] Distribution ratios for lithium iodide and lithium iodide–ammonium iodide mixtures between ethylene glycol and ethyl acetate were determined[30] at 30°C. Aqueous lithium iodide solutions can dissolve urea-formaldehyde resins.[31]

TABLE II.- SOLUBILITY OF LITHIUM IODIDE IN METHANOL, ACETONITRILE AND FORMIC ACID

Solvent	*t*°C.	*S* (g./100 g. of solvent)
Methanol	18	143

Acetonitrile	18	147
	25	154
Formic acid	18	139
	25	146

The theory of the viscosity of electrolyte solutions has been extended by introducing the concept of closest approach, but comparison of the values calculated for lithium iodide and other uni-univalent electrolytes with the experimental values shows that the treatment gives no improvement on the older theory.[32]

The freezing point constant at zero concentration of lithium iodide dissolved in calcium chloride hexahydrate, $CaCl_2,6H_2O$, has been determined as 66·4 and its significance discussed.[33] The vapour pressures of aqueous solutions of lithium iodide relative to those of potassium chloride solutions have been determined[34] by an isopiestic method; the results are given in Table III where m_1 is the molar concentration of the potassium chloride solution and m_2 that of the isopiestic solution of lithium iodide.

TABLE III.- ISOPIESTIC AQUEOUS SOLUTIONS OF POTASSIUM CHLORIDE AND LITHIUM IODIDE

0·7964	0·6852			4·81	3·152

The molecular weight of lithium iodide in nitrobenzene varies from 270 to 365; the formula weight of lithium iodide, LiI, is 133·86, hence the 270 value is approximately double and is evidence that lithium iodide polymerizes in nitrobenzene.[28]

The decomposition potential of fused lithium iodide is 2·48 V. and this experimental value agrees with those calculated by two different methods.[35]

The theory of the electrical conductivity of aqueous solutions of electrolytes has been extended by introducing the concept of closest approach; complete quantitative agreement of the calculated values with experiment is found for lithium iodide and other uni-univalent electrolytes at concentrations less than 0·1 N.[32] The molar conductivity of aqueous solutions of lithium iodide has been measured.[36] The conductivities of solutions of various concentrations of lithium iodide in iodine were measured at various temperatures; the specific conductivity increases with concentration of the iodide and reaches a maximum of $1{\cdot}1 \times 10^{-1}$ ohm^{-1} cm.$^{-1}$ at 130°C.; the molar conductivity of a

24·16% solution of lithium iodide at 130° is 13·66 cm.^{2} mole^{-1} ohm^{-1}; the temperature coefficient of the specific conductivity is negative at small concentrations of lithium iodide and becomes positive at higher concentrations; the conductivity of iodide solutions in iodine is conditioned by the polymerization of polyiodides, the polymers dissociating electrolytically,[37] *e.g.*:-

$$(LiI_3)_2 \rightleftharpoons Li^+ + LiI_6^- \text{ or}$$
$$(LiI_3)_2 \rightleftharpoons I^- + Li_2I_5^+.$$

The conductivities at 4°, 15° and 25°C. of solutions of lithium iodide in ethyl alcohol have been measured; values of the equivalent conductivity are given in Table IV and of the limiting conductivity and dissociation constant in Table V; the mean heat of dissociation was calculated as 12·9 kg.-cal. from 4° to 15°C. and as 5·8 kg.-cal. from 15 to 25°C.[38]

t°C.	Limiting Conductivity	Dissociation Constant
4	28·92	0·412
15	36·08	0·172
25	43·80	0·121

The conductivities at 25°C. of lithium iodide in 0·0001–0·002N-nitromethane solutions have been measured and the limiting conductivity was found to be 117·5; the deviation of this value from the value calculated from the Debye–Hückel–Onsager equation is ascribed to ionic association of lithium iodide in nitromethane.[39] The conductivities of solutions of lithium iodide in benzonitrile have been measured[40] at 0°, 25° and 50°C.; the results, which are given in Table VI, are interpreted as showing that, except in extremely dilute solution, lithium iodide is incompletely dissociated. From the measured conductivities in benzonitrile and the dielectric constant of the solvent, the dissociation

TABLE VI.- EQUIVALENT CONDUCTIVITY OF LITHIUM IODIDE IN BENZONITRILE (v = dilution in litres)

v	0°C.	25°C.	50°C.

10,000	27·96	44·35	62·38

Refs. p. 236

constant of lithium iodide is calculated[41] to be 8×10^{-3} at 25°C. The conductivities of 0·0005 N. to 0·1 N. solutions of lithium iodide in furfural indicate that furfural is a solvent possessing high dissociating power and the degree of solvation of the salt cation is approximately of the same order of magnitude as in aqueous solution.[42] In methyl cyanide, lithium iodide is a strong electrolyte.[43] The electrical conduction of the vapour of lithium iodide has been studied.[44]

The Soret coefficient of lithium iodide, as measured in a diffusion apparatus, is $-2{\cdot}3 \pm 0{\cdot}2$ milliunits per degree;[45] similar measurements gave the coefficient as $-1{\cdot}35 \times 10^{-3}$ at 30°C. increasing to $0{\cdot}42 \times 10^{-3}$ at 60°C. and show that the coefficient is temperature-dependent;[46] the Soret coefficient of lithium iodide, and of other uni-univalent electrolytes, can be obtained by the summation of the coefficients of the single ions.[45,46]

The activity coefficient of lithium iodide in aqueous solution has been determined from vapour pressure measurements as between 0·8 and 1·7 in the concentrations studied[34] and the stoicheiometric activity coefficient has been derived from distribution studies.[30]

Lithium iodide is a very effective catalyst for the mutarotation of glucose in pyridine solution.[47] The reversible S_N2 reaction, alicyclic bromide + I^- = alicyclic iodide + Br^-, has been studied using lithium iodide in anhydrous acetone.[48]

The difference in the dipole moments of ^6LiI and ^7LiI, due to isotopic substitution, is $2{\cdot}6 \times 10^{-21}$ millidebyes.[49] The mass spectrum of lithium iodide has been determined[9] at 700° abs.; the appearance potentials for the major ions in the spectrum are presented in Table VII.

TABLE VII.- APPEARANCE POTENTIALS IN MASS SPECTRUM OF LITHIUM IODIDE

m/e	Ion	Appearance potential in electron volts
134	$^7LiI^+$	$8{\cdot}55 \pm 0{\cdot}15$
141	$^7Li_2I^+$	$8{\cdot}75 \pm 0{\cdot}10$
7	Li^+	$9{\cdot}2 \pm 0{\cdot}15$
7	Li^+	$11{\cdot}75 \pm 0{\cdot}20$
127	I^+	$14{\cdot}5 \pm 0{\cdot}20$

Chemical Properties

When anhydrous lithium iodide is heated in pure dry oxygen, iodine is liberated and lithium oxide and iodate are formed.[50] Electrolysis of lithium iodide in anhydrous acetic acid using a silver anode results in the formation of silver iodide in quantitative yield.[51]

Spectrophotometric measurements on butyl alcohol solutions containing lithium iodide and cobalt (II) perchlorate have shown the existence of the complex cobalt (II) pentaiodide ion, $[CoI_5]^{-3}$, which on dilution dissociates to form the complex cobalt (II) tetraiodide ion, $[CoI_4]^{-2}$.[52] Similar spectrophotometric measurements have shown that in ethyl alcohol solution iodide ion, added as lithium iodide, displaces chloride ion from the complex cobalt (II) tetrachloride ion, $[CoCl_4]^{-2}$, less readily than does bromide ion, added as lithium bromide.[53]

β-Alanine, $H_2NCH_2{\cdot}CH_2{\cdot}CO_2H$, gives two addition compounds with lithium iodide:

$$H_2NCH_2{\cdot}CH_2{\cdot}CO_2H,\ LiI, 1{\cdot}5H_2O;$$
$$\text{and } 2H_2NCH_2{\cdot}CH_2{\cdot}CO_2H, LiI, 1{\cdot}5H_2O.^{54}$$

Refs. p. 236

The 1:1 co-ordination complex of lithium iodide and dimethyl formamide, $LiI,HCON(CH_3)_2$, has been prepared and its properties studied.[55]

Lithium iodide in methyl cyanide exchanges iodine with butyl iodide; the process involves the iodide ion, I .[43]

Nessler reagent prepared with lithium iodide instead of potassium iodide is extremely sensitive.[56]

Examination of the system PbI_2–LiI–H_2O shows that the only double salt is $PbI_2,LiI,4H_2O$,[57] although at higher temperatures there are indications of a double salt containing less water.[58] The effect of lithium iodide on the solubility of thallium iodide in various solvents was studied and found to give rise to the double salt $LiTlI_4$.[59] Mixed crystals of lithium iodide and sodium sulphate have been prepared containing from 0–0·57% of iodine.[60]

Applications

Lithium iodide has been used as a constituent of disinfectants.[61] The effect of lithium iodide on cellulose dispergation has been studied.[62]

Lithium iodide has been used to effect dehydrobromination of the 4-Br derivative of 17α-hydroxy-21-acetoxypregnane-3,11,20-trione in dimethylformamide.[55]

SECTION XIV

LITHIUM SULPHIDE

By C.W. GROGAN

Lithium sulphide is prepared from the hydrosulphide (see below). When the alcohol–hydrosulphide complex is rapidly heated to 360°C. *in vacuo*, both lithium sulphide and lithium ethoxide are formed, and on passing a stream of gas containing 90% of hydrogen and 10% of hydrogen sulphide over the residue at 120°C., lithium hydrosulphide is formed. If this is heated to 360°C. in the presence of solid potassium hydroxide and phosphorus pentoxide, nearly pure lithium sulphide is formed. The disulphide is also prepared by the addition of sulphur to an alcoholic solution of the hydrosulphide.[1]

Other methods employed for the preparation of the sulphide include direct synthesis from sulphur and lithium in liquid ammonia, and the reduction of lithium sulphate monohydrate by hydrogen in the silent electric discharge, according to the equation:-

$$Li_2SO_4 + 4H_2 \rightarrow Li_2S + 4H_2O$$[2-5]

Lithium sulphide has a calcium fluoride structure, with a lattice constant = 5•708 A. determined by the powder method.[3]

Lithium sulphide has been used in the preparation of electroluminescent materials, in the formation of corrosion inhibitors for steels in contact with hydrocarbon oils and in the preparation of mixed alkyl-alicyclic disulphides.[6-8]

Lithium hydrogen sulphide.

Lithium hydrogen sulphide has been prepared by the action of hydrogen sulphide on lithium ethoxide. The ethoxide is prepared by the action of lithium chloride solution in alcohol on an alcoholic solution of sodium ethoxide, the precipitated sodium chloride being filtered off under hydrogen and the lithium ethoxide isolated by evaporating the solution at 70°C. The action of hydrogen sulphide on the alcoholate in dry ether forms $2LiHS,EtOH$ as a very deliquescent, pure white powder which is decomposed rapidly by carbon dioxide. The molecule of alcohol cannot be removed without causing the decomposition of the hydrosulphide. Pure lithium hydrosulphide can be prepared by the action of hydrogen sulphide on lithium in dry ether, the purity of the metal being the limiting factor.[9]

By replacing the lithium ethoxide by lithium amyloxide in ether and passing a slow stream of hydrogen sulphide, a colourless precipitate turning yellow in air is obtained. It decomposes at 50°C. *in vacuo*. It has a tetragonal structure with $a = 5{\cdot}54$, $c = 12{\cdot}31$kX. and there are 8 mols. per unit cell. The following data were obtained:-[10] $d_{25^\circ} = 1{\cdot}38$. Heat of solution $\Delta H = 8{\cdot}5$kg.-cal./mol. Heat of formation $\Delta H = -60$kg.-cal./mol. For $2LiOH + H_2S = Li_2S + H_2O$ $\Delta H = 6{\cdot}4$kg.-cal./mol.

Lithium polysulphides.

Four routes have been explored for the preparation of these polysulphides:-

(1) The action of sulphur on lithium sulphide in alcohol, aqueous alcohol, and aqueous solutions resulting in solutions containing polysulphides which cannot be crystallized.

(2) The action of sulphur on lithium hydrosulphide in anhydrous alcohol; the primary product is lithium tetrasulphide (Li_2S_4), provided that the sulphur is present in the quantity required by the equation:-

$$2LiHS + 3S \rightarrow Li_2S_4 + H_2S$$

The ethyl alcohol complex $Li_2S_4,2C_2H_5OH$ crystallizes from the solution at room temperature while at the boiling point Li_2S_2,C_2H_5OH is obtained. When lesser proportions of sulphur are used a mixture of Li_2S_4 and LiHS results.

(3) The action of sulphur on dry lithium carbonate or hydroxide.[11] This yields polysulphides and higher oxidation products, e.g. - at 200°C. - thiosulphate and polysulphide; at 400°C. - some sulphur and thiosulphate; at 700°C. - polysulphide and sulphate together with small quantities of thiosulphate and sulphite.

(4) The action of sulphur on molten lithium. Here there is no reaction until 0·5g.-atom of sulphur has been added to 1g.-atom of lithium, when an explosive reaction occurs, forming lithium sulphide and small quantities of polysulphide. A study of the lithium sulphide–sulphur system shows that at atmospheric pressure only lithium sulphide (Li_2S), (stable at its m.p. 900°–975°C.) and lithium disulphide (Li_2S_2) (slightly decomposed at its m.p. 369·5°C.) are stable.[12]

SECTION XV

LITHIUM SULPHATE

By C.W. GROGAN

Recent studies on the preparation of pure lithium sulphate have shown that the addition of ethyl alcohol to solutions acidified with dilute hydrochloric acid precipitates the pure salt,[1] while the solubility isotherm for the ternary system $LiCl$–Li_2SO_4–H_2O indicates that the sulphate is precipitated quantitatively from lithium chloride solution.[2] It is also insoluble in liquid ammonia.[3]

Large crystals of lithium sulphate may be grown under controlled conditions of pH. Initial growth of a seed crystal in a solution of pH 4–5 is followed by further growth at pH 6–7 which develops the crystal lengthwise. At fixed temperatures, crystals 3–4in. long have been grown in about four weeks. These are very liable to have flaws.[4-6] The incidence of twinning and the mechanism of spiral growth of such crystals have been investigated.[7]

The isotopic assay of lithium may be carried out by measuring the intensity of selected lithium hydride bands for ^6LiH and ^7LiH when lithium sulphate samples are subjected to low current d.c. arc excitation in an atmosphere of 50% helium and 50% hydrogen.[8]

The crystal structure of lithium sulphate has been established from a number of investigations involving Laue and rotation photographs; measurements of nuclear magnetic resonance have defined the position of the water molecules in the crystalline hydrate.

From the Laue and oscillation photographs on the anhydrous salt, the monoclinic unit cell contains four molecules, the constants being: $a = 8{\cdot}25$A., $b = 4{\cdot}95$A., $c = 8{\cdot}44$A., and $\beta = 107°54'$. The sulphate groups form regular tetrahedra with the sulphur–oxygen distance 1·50A., and the oxygen–oxygen distance 2·45A.; each lithium atom is surrounded by four oxygen atoms each from a sulphate group, forming a nearly regular tetrahedron, with the average lithium–oxygen distance 1·97A., and oxygen–oxygen distance 3·20A.[9]

In the crystalline hydrate (Li_2SO_4,H_2O), the monoclinic unit cell contains two molecules with $a = 5{\cdot}43$A., $b = 4{\cdot}8$A., $c = 8{\cdot}14$A., and $\beta = 107°35'$ with the oxygen of the water molecule at one corner of an oxygen tetrahedron surrounding the lithium atom. The H–O–H angle is 108° and the sulphur–oxygen bonds substantially the same as in the anhydrous salt.[10,11]

In a determination of the crystalline structure of the hydrate employing nuclear magnetic resonance methods on powders and single crystals, measurements of the fine structure of the absorption spectrum in the high frequency region are related to distortion of the water molecules. The hydrogen atoms are $1{\cdot}57 \pm 0{\cdot}02$A. apart on a line making an angle of $46° \pm 2$ with the binary axis of the crystal.[12,13]

In a more recent determination of the magnetic resonance of a single monohydrate crystal, the H–H distance is 1·59A. If the O–H distance is assumed to be 0·99A., the H–O–H angle will be 106°50'. From the O–O distance measured however, such a value for the H–O–H angle seems unlikely, and an O–H distance nearer to that in water vapour than to that in ice is suggested, when the H–O–H angle becomes 112°40'.[14]

Since a correlation has been observed between hydrogen bonding and an increase in molar volume on replacing hydrogen by deuterium in the hydrate, the figures given in Table I for lithium sulphate hydrate and deuterate are interesting, since they give only negative evidence for the existence of such bonds. It is concluded, however, that absence of expansion when D_2O replaces H_2O does not necessarily imply absence of hydrogen bonding.[15]

TABLE I.- DENSITY AND MOLAR VOLUME OF LITHIUM SULPHATE HYDRATE AND DEUTERATE

	d_4^{20}	Molar Vol.
Li_2SO_4,H_2O	2·051	62·2
Li_2SO_4,D_2O	2·127	61·1

Many studies of the solubility and of the vapour pressure of lithium sulphate have been made, and results are summarised in Tables II and III.

TABLE II.- SOLUBILITY OF LITHIUM SULPHATE IN WATER[16,17]

Temp. °C.	Solubility[16]	Temp. °C.	Solubility[17]
−16	27·32	142·5	22·65
0·6	26·51	186	22·7
19·6	25·85	214	23·0
103	23·72		

TABLE III.- VAPOUR PRESSURE OF LITHIUM SULPHATE SOLUTIONS[18]

Temp. °C.	V.p., mm. Hg	Temp. °C.	V.p., mm. Hg
25·3	20·85	89·65	458·0
30·65	28·5	99·50	657·7
45·65	64·5	100·1	676·4
60·15	129·6	105·25	799·0
69·4	197·3	110·35	945·7
84·3	349·9		

The monohydrate is stable down to −8°C., but at lower temperatures there is a possibility that a dihydrate exists.[16] For the system lithium sulphate-water, the transition temperature of the reaction $Li_2SO_4,H_2O \rightarrow Li_2SO_4 + H_2O$ occurs at 232·8°C. and 26·7atm.[17] A thermal analysis of the hydrate shows a loss of water at about 210°C., a large endothermic effect at 600°C., presumably due to an inversion, and the m.p. at 880°C.[19]

Measurements of the integral heat of dilution (L) of 1/g. equiv. of lithium sulphate in hydrochloric acid of varying concentration have been made during a study of the hydration of the ions of the alkali metals. For lithium the co-ordination number is almost 3·8, nearly the same as that of water.

The value dL/dm (where m is the concentration of hydrochloric acid in the individual solution - 50mols. H_2O + m mols. HCl) is approximately constant between $m = 0{\cdot}84$ and 3·51.[20] For aqueous solutions between 10^{-1} and 10^{-4}M., the integral heats of dilution V_m, and differential heats of dilution Φ_m (m = molar concentration) are positive at the highest dilution, but pass through a maximum when m is still very small and ultimately become negative with further rise in m.[21]

Thermodynamic data for lithium sulphate have been extensively studied and values of $\Delta H°$, $\Delta F°$, and $\Delta S°$ are given for the synthesis of lithium sulphate and for the heat of formation of the hydrate.

From measurements at 20–30°C., of the E.M.F. of the reversible cell

$$\text{Li-Hg } (0{\cdot}035\%) \mid Li_2SO_4,H_2O \text{ (satd. soln.) } Hg_2SO_4 \mid Hg,$$

$$E = 2{\cdot}67489 - 0{\cdot}000241\,(t - 25) \text{ volts.}^{22}$$

and for the reaction, $2Li_{(s)} + S_{(s,\alpha)} + 2O_{2(g)} \rightarrow Li_2SO_{4(s)}$, at 25°

$$\Delta H^\circ_{298\cdot1} = -338099\text{g.-cal.}$$
$$\Delta F^\circ_{298\cdot1} = -313614\text{g.-cal.}$$
$$\Delta S^\circ_{298\cdot1} = -82\cdot3\text{g.-cal./}^\circ\text{C.}$$
$$S^\circ_{298\cdot1} = 38\cdot7\text{g.-cal./}^\circ\text{C./mol.}$$

These values were confirmed in a later determination[23] and extended to cover the range 360°–1270°K.[24]

e.g. Heat of conversion at 859°K. = 6530·7g.-cal./mol.
Heat of melting at 1133°K.(m.p.) = 1833·0g.-cal./mol.
Entropy of melting = 1·6g.cal./mol./degree.

For the reaction $Li_2SO_{4\,(s)} + H_2O \rightarrow Li_2SO_4,H_2O$, at room temperature,

$$\Delta H = -3018\text{g.-cal.}$$

and the vapour pressure of the hydrate at 298·1°K. is $9\cdot21 \times 10^{-3}$atm.

Thus $\Delta F^\circ_{298\cdot1}$ for $H_2O_{(g)} = -2775$g.-cal. and for $H_2O_{(l)} = -721$g.-cal.[23]

As is shown in Tables IV and V the conductivity of lithium sulphate in aqueous and acidic media has been studied; the degree of dissociation of the salt has also been evaluated, and evidence obtained for the existence of the bisulphate ion.

The dissociation constant for $LiSO_4^-$ is 0·229.[25]

TABLE IV.- SPECIFIC CONDUCTIVITY OF AQUEOUS LITHIUM SULPHATE AT 25°C.[26]

Concentration(M)	Conductivity(κ)	Concentration(M)	Conductivity(κ)
0·003928	0·00080882	0·12701	0·017224
0·019680	0·0035167	0·24602	0·028902
0·053930	0·0084570	0·53770	0·050041

TABLE V.- EQUIVALENT CONDUCTIVITY OF LITHIUM HYDROGEN SULPHATE

Concentration, N.	100κ	Λ
0·1	1·52	152
0·2	2·17	108
0·4	3·37	84·2
0·6	4·24	70·7
0·8	4·80	60·0
1·0	5·33	53·3
1·2	5·57	46·4
1·4	5·80	41·4

The conclusion is reached that the solution of lithium sulphate in sulphuric acid yields one HSO_4^- ion per mol. and since the equivalent conductivity of the cation is low, the decreasing conductivity with increasing concentration is due to interferences with a chain mechanism of conduction by HSO_4^-, since an increase in the bisulphate ion concentration increases the chance of two chains interfering with one another. The solvation of the cation also reduces the freedom of motion of some solvent molecules.[27] An extension of the work to include measurements of viscosity and density in sulphuric acid solutions confirmed the solvation number of Li^+ as 3 and showed that both the density and the viscosity of the solutions increase proportionally with concentration up to 1·8 molal.[28]

In the presence of high concentration of cane sugar the conductivity-concentration relationship of lithium sulphate solutions showed high mobilities for the cation and this is attributed to the decrease in ion radius due to the lower degree of hydration of the ion.[29]

The activity coefficients of lithium sulphate and of lithium hydroxide and sulphuric acid in lithium sulphate solutions have been determined and compared with theoretical values.[30] Confirmation of these results has also been obtained from isopiestic measurements with solutions of potassium chloride.[31]

The cell,

$$Hg \mid Hg_2SO_4 \mid Li_2SO_{4(c)} \mid LiHg \mid Li_2SO_{4\,(c_1)} \mid Hg_2SO_4 \mid Hg,$$

where c_1 is the reference and c the salt concentration, avoids liquid junction potentials and gave the results shown in Table VI.

TABLE VI.- ACTIVITY COEFFICIENTS FOR LITHIUM SULPHATE SOLUTION[32]

Concn., M.	E.M.F. (volts)	γ obs.	γ calc.
0·025	−0·02051	0·613	0·613
0·05	0·0	0·522	0·535
0·125	+0·02744	0·425	0·432
0·25	0·04809	0·364	0·363
0·5	0·06838	0·308	0·308
1	0·08904	0·263	0·269
1·5	0·10408	0·259	0·253
2·0	0·11432	0·254	0·248

The activity of sulphuric acid in lithium sulphate has been determined using a cell of the type:-

$$H_2 \mid H_2SO_{4(c_1)}\,Li_2SO_{4(c)} \mid Hg_2SO_4 \mid Hg.$$ [32]

The equivalent refractivity of lithium sulphate solutions is dependent upon concentration[33] and these results have been used in the evaluation of the degree of dissociation of the salt in fused glass. In comparison with the refractive index of the pure salt and its aqueous solutions at infinite dilution, the values for borax glass are less than expected and the difference is attributed to the strong deformation and meagre dissociation which the salt suffers in the glass medium.[34]

In contrast, the determination of magnetic susceptibility of lithium sulphate in borax glass, using a torsion balance, gives values much larger than those for the pure salt, indicating an expansion of the lattice.[35]

Conductometric methods have also been applied to the determination of the diffusion coefficients of lithium sulphate, and the results given in Tables VII and VIII are in agreement with values calculated from the theory of Fuoss and Onsager.

TABLE VII.- DIFFUSION COEFFICIENT OF LITHIUM SULPHATE AT 25°C.[36,37]

Concn., M.	Diffusion Coefficient	
	Obs.	Calc.
0·00071	0·997–8	0·998
0·0021	0·973	0·975
0·00348	0·961	0·961
0·0044	0·954	0·955
0·00573	0·946	0·948

The value of the Soret coefficient for lithium sulphate is 1·4 ± 0·1milli-units/°C. and the heats of transference (relative to the chloride ion) calculated from this value are $Li^+ = 0{\cdot}0$, $SO_4'' = 0{\cdot}7$kg.-cal./mol.[39]

TABLE VIII.- DIFFUSION RATE OF LITHIUM SULPHATE[38]

Concn.	Diff. Rate
0·1N.	0·685
1N.	0·626
4N.	0·574

Examination of the lithium sulphate crystal for piezoelectric and elastic properties shows that the salt is piezoelectrically positive[40,41] and, from *X*-ray data over the range −30°C. to +25°C., that thermal expansion is negative in a 45° range roughly normal to *c* in the *a*–*c* plane. The secondary and total pyroelectric constants of lithium sulphate are 21×10^{-6} and 76×10^{6} coulomb/m.^{2}/°C.[42] The dielectric constant has also been determined as a function of temperature over the range 100–400°K. at 500–20,000c./s. for the crystalline hydrate, and it is concluded that there is little chance of lithium sulphate being ferroelectric below −180°C.[43]

The Raman inactive frequency of lithium sulphate (hydrate) in benzene is 1003·1cm.$^{-1}$, and measurements have also been made on N. and 2N. aqueous solutions.[44]

The thermal stability of lithium sulphate has been studied in comparison with that of sodium and potassium sulphates: the conclusion reached is that a decrease in ionic character of the bond is due to the polarising action of the lithium ions on the anion.[45] The volatility of lithium sulphate as compared with sodium and potassium sulphates is given in Table IX.

TABLE IX.- VOLATILITY OF ALKALI METAL SULPHATE

Temp. °C.	Duration of expt.	Loss in wt.-%		
		Li_2SO_4	Na_2SO_4	K_2SO_4
800		Nil	Nil	Nil
900	2hr.	0·12	Nil	Nil
1000	2hr.	0·51	0·04	0·12
1200	2hr.	1·76%/hr.	0·52%/hr.	1·82%/hr.

The presence of $(Li_3SO_4)^+$ and $(LiSO_4)^-$ in pure molten lithium sulphate is shown by a study of the eutectics of the binary systems Li_2SO_4–$BaSO_4$, Li_2SO_4–$SrSO_4$, Li_2SO_4–$PbSO_4$; by the depression of freezing point of lithium sulphate by small amounts of other metal sulphates; and by the depression of the freezing point of potassium nitrate by small additions of lithium sulphate. Dissociation into Li^+ and $(LiSO_4)^-$ occurs when the concentration of lithium sulphate is moderate, but at low concentrations dissociation yields[46] Li^+ and SO_4^{2-}.

The surface tension of molten lithium sulphate, determined by the maximum bubble pressure method, is:- at 900°C., 224dynes/cm.; at 1100°C., 211dynes/cm.[47]

A photographic study of the diffusion of lithium sulphate in a bunsen flame indicates that at a flame temperature of 1436°C. polymerization of the lithium sulphate is probably responsible for the low rate of diffusion.[48]

Many binary, ternary and quaternary systems involving lithium sulphate have been studied in both aqueous and fused media.

(1) Li_2SO_4–Na_2SO_4–H_2O

When aqueous solutions of sodium sulphate and lithium sulphate are maintained at 27°C. for 24hr. and the solid products in equilibrium with the saturated solution are analysed, three solid phases are found, $Na_2SO_4,10H_2O$, $Na_3Li(SO_4)_2,6H_2O$ and Li_2SO_4,H_2O, while the solution in equilibrium with the solid phase contained Li_2SO_4 5·4%, Na_2SO_4 25·5%, H_2O 69·1%.

Four solid phases (the fourth being $NaLiSO_4$) were reported in a similar experiment carried out at 46·5°C.[49]

The 0°C. isotherm is similar except for the numerical relationships.[50]

(2) Li_2SO_4–$(NH_4)_2SO_4$–H_2O

This system exhibits two ternary eutectics:-

(a) $(NH_4)_2SO_4$–$(NH_4)_2SO_4,Li_2SO_4$–Ice at −27°C.
(b) Li_2SO_4–$(NH_4)_2SO_4,Li_2SO_4$–Ice at −30°C.

The heat of formation of the double salt is 1·28 ± 0·01kg.-cal.[51]

(3) Li_2SO_4–$M^{++}SO_4$

Double salts of the type:-

$$Li_2SO_4,M^{++}SO_4 \text{ and } 2Li_2SO_4,M^{++}SO_4$$

are formed from zinc, copper, magnesium, cobalt, nickel and vanadium sulphates, although silver sulphate forms only one double salt, Ag_2SO_4,Li_2SO_4.[52] Cadmium sulphate, however, does not appear to form a double salt,[53] and the existence between 0° and 35°C. of the copper sulphate double salt is also questioned.[54]

(4) Li_2SO_4–$M^{3+}{}_2(SO_4)_3$

Bismuth sulphate forms two double salts, viz:-

$$3Li_2SO_4,Bi_2(SO_4)_3,4H_2O$$
$$Bi_2O_3,SO_3,LiSO_4,2H_2O$$[55]

Early attempts to prepare lithium alum proved unsuccessful,[56,57] but a double salt incongruently soluble at 0°C. has recently been obtained.[58]

(5) Li_2SO_4–K_2SO_4

Li_2SO_4,K_2SO_4 is formed at 25°C. as the solid separating from solutions containing the two salts, but is considered as only a borderline case of a series of solid solutions which are formed of composition mLi_2SO_4,nK_2SO_4 giving K:Li limits varying from 1:1 to 1:1·08.[59] The crystal structure of $LiKSO_4$ consists of a system of SO_4'' ions in hexagonal close packing alternating with metallic ions.[60]

The equilibrium curves for solutions of the double sulphates of lithium, sodium and potassium with aqueous sulphuric acid have also been studied[61] as has also the four component system Li_2SO_4–$(NH_4)_2SO_4$–H_2SO_4–H_2O.[62]

Binary, ternary and quaternary systems in the molten state have been studied, and many reported eutectics incorporating lithium sulphate are summarised in Table X.

The existence of a eutectic between potassium sulphate and lithium sulphate has also been confirmed by specific conductivity measurements between 266°C. and 1068°C. The conductivity/temperature relationship is then

$$\log K = a + bT$$

where a and b are constants and K is the specific conductivity.[75] The double salts of sodium and potassium sulphates with lithium sulphate have differing hexagonal structures, but though no solid solutions appear to exist between them,[76] the decomposition and other changes occurring during cooling suggest that sodium sulphate does form such a solution.[77]

In an extension of the binary systems of sodium and potassium sulphates with lithium sulphate to the ternary system with potassium nitrate, the phase diagram has five regions where the solid phases and the percentages of the total area they represent are respectively;- K_2SO_4 43·2%; Li_2SO_4 42·7%; Li_2SO_4,K_2SO_4 12%; KNO_3 0·8%; $LiNO_3$ 1·3%.

There are three invariant points:-

(1) A transition point at 440°C. containing 53·5 (equiv.) % SO_4, 58% Li.
(2) A transition point at 133°C. containing 1% SO_4, 43·5% Li.
(3) A eutectic at 103°C. containing 1·0% SO_4, 41·5% Li.[78]

Refs. p. 247

Li_2SO_4-Li_2WO_4	630			69
Li_2SO_4-Li_2WO_4	854			
Li_2SO_4-Li_2MoO_4	564	62·5	Li_2SO_4	70
Li_2SO_4-Na_2Cl_2-K_2Cl_2	426	24	K_2Cl_2	71
		17	Na_2Cl_2	
		59	Li_2SO_4	
Li_2SO_4-Na_2SO_4-K_2SO_4	512	79	Li_2SO_4	72
		9	Na_2SO_4	
		12	K_2SO_4	
Li_2SO_4-Li_2Cl_2-Li_2WO_4	444	47	Li_2Cl_2	73
		21	Li_2WO_4	
		32	Li_2SO_4	
Li_2SO_4-$CdCl_2$-$CdSO_4$	512			67
Li_2SO_4-Li_2Cl_2-$ZnCl_2$	285	0·5	Li_2SO_4	74
		13	Li_2Cl_2	
		86·5	$ZnCl_2$	
Li_2SO_4-$ZnCl_2$-$ZnSO_4$	293	0·7	Li_2SO_4	74
		90·3	$ZnCl_2$	
		9·0	$ZnSO_4$	

The reaction between lithium chloride and zinc sulphate is irreversible,

$$Li_2Cl_2 + ZnSO_4 \rightarrow Li_2SO_4 + ZnCl_2,$$

two binary compounds occurring:-

(*a*) $Li_2Cl_2,ZnCl_2$ (incongruent m.p. 352°C.)
(*b*) $ZnCl_2,ZnSO_4$ (incongruent m.p. 437°C.)

Eight fields of crystallization of the solid phases were established in the system Li,Zn || Cl,SO_4 corresponding to α- and β-Li_2SO_4, α- and β-LiCl, $ZnCl_2$, $ZnSO_4$, and the compounds (*a*) and (*b*). The system exhibits two ternary eutectic points:-

(1) at 285°C. - Li_2Cl_2 13, Li_2SO_4 0·5 $ZnCl_2$ 86·5mol.%
(2) at 293°C. - Li_2SO_4 0·7 $ZnCl_2$ 90·3 $ZnSO_4$ 9mol.%

and two transition points at 330°C. and 397°C.[74]

When cadmium sulphate replaces the zinc sulphate of the former system, an irreversible reaction occurs:-

$$CdSO_4 + Li_2Cl_2 \rightarrow Li_2SO_4 + CdCl_2 \ (\Delta H = 7{\cdot}99\text{kg.-cal./equiv.})$$

Refs. p. 247

involving three eutectics:-

(a) CdCl$_2$–CdSO$_4$ m.p. 542°C. 15% CdSO$_4$
(b) Li$_2$SO$_4$–CdSO$_4$ m.p. 550°C. 32% CdSO$_4$
(c) Li$_2$Cl$_2$–Li$_2$SO$_4$ m.p. 478°C. 53% Li$_2$SO$_4$,

while CdCl$_2$–Li$_2$Cl$_2$ exhibits continuous solid solutions, with a minimum at 500°C., containing 77–78% CdCl$_2$ (d).

The four salts are represented at opposite corners of a square phase diagram, and the only stable cross-section consists of a diagonal joining cadmium chloride and lithium sulphate with a eutectic at 543°C. containing 3·5% Li$_2$SO$_4$. This divides the square into two ternary systems, CdCl$_2$–Li$_2$SO$_4$–Li$_2$Cl$_2$ containing the solid solutions Li$_2$Cl$_2$–CdCl$_2$ and the field of crystallization of Li$_2$SO$_4$; and CdCl$_2$–Li$_2$SO$_4$–CdSO$_4$, with a ternary eutectic, m.p. 512°C. The immiscibility is attributed to the different electronic structures of the cations.[67]

In the three dimensional diagram of the Li$_2$SO$_4$–K$_2$SO$_4$–K$_2$WO$_4$ system, the two sections representing varying proportions of Li$_2$WO$_4$,K$_2$WO$_4$ to Li$_2$SO$_4$, K$_2$SO$_4$, and Li$_2$WO$_4$ to Li$_2$SO$_4$,K$_2$SO$_4$ are stable, and all other sections metastable. Reactions in the system therefore tend towards the formation of Li$_2$SO$_4$,K$_2$SO$_4$ and Li$_2$WO$_4$,K$_2$WO$_4$. The system exhibits three eutectics:- (*a*) at 480°C. Li$_2$WO$_4$ 20%; K$_2$SO$_4$ 20%; Li$_2$SO$_4$ 60%; (*b*) at 484°C. Li$_2$WO$_4$ 30%; K$_2$WO$_4$ 37·5%; Li$_2$SO$_4$ 32·5%; (*c*) at 486°C. Li$_2$WO$_4$ 47·0%; K$_2$SO$_4$ 37·5%; K$_2$WO$_4$ 15·5%; and a transition point at 526°C.[79]

Other systems investigated include:-

(*a*) the ternary system Li || Cl, SO$_4$, WO$_4$ eutectic m.p. 444°C. 32% Li$_2$SO$_4$, 47% Li$_2$Cl$_2$, 21% Li$_2$WO$_4$[73]
(*b*) the ternary system Li, Na, Ca || SO$_4$[77]
(*c*) the reciprocal system Li, K || SO$_4$, PO$_3$[80]
(*d*) the ternary system Li, Na || NO$_3$, SO$_4$[81]
(*e*) the ternary system Li, K || SO$_4$, BO$_2$[82]
(*f*) the ternary system Li, K || MoO$_4$,SO$_4$[70]
(*g*) the quaternary system Li, Na, K || SO$_4$, Cl[71]
(*h*) the quaternary system Li, Na, K, Tl || SO$_4$[83]
(*i*) the quaternary system Li, K || Cl, SO$_4$, WO$_4$[84]

In the estimation of lithium sulphate by precipitation as barium sulphate, the precipitate is liable to be contaminated by coprecipitation of lithium sulphate. Solid solutions of substitutional type are formed containing BaSO$_4$, Li$_2$SO$_4$ and water, for low concentrations of Li$^+$. For precipitates of higher lithium concentration, solid solutions of BaSO$_4$, LiHSO$_4$, Li$_2$SO$_4$ and water are indicated which contain one mol. of water per Li$^+$, retained after extensive drying at 110°C.[85] A suitable analytical procedure has been developed for the estimation of lithium sulphate by precipitation as barium sulphate.[86]

Lithium sulphate has been employed in the preparation of hydrogen peroxide[87] and persulphates[88] by electrolysis, and the oxygen overpotential in the fused melts of lithium sulphate in lithium sodium fluoride has also been studied.[89]

Lithium sulphate also finds application in the preparation of catalysts for the dehydrogenation of *cyclo*hexanol and *cyclo*hexanone to phenol[90] and in the preparation of casting material in conjunction with gypsum.[91]

Lithium sulphate solutions containing acidified ferrous sulphate are oxidized by thermal neutrons and the neutron dose may thus be followed from the course of oxidation of the iron.[92]

SECTION XVI

LITHIUM CARBONATE

By R. E. OLIVER

Preparation and Production

Lithium carbonate may be prepared in the laboratory by the following methods.

(*i*) The double decomposition of a solution of a lithium salt with a solution of an alkali metal carbonate. Probably the most frequently used reaction of this type is that between lithium sulphate and sodium carbonate, $Li_2SO_4 + Na_2CO_3 \rightarrow Li_2CO_3 + Na_2SO_4$.

Owing to the appreciable solubility of lithium carbonate in solutions of other salts, a recovery of only about 75% can be achieved. Lithium carbonate prepared in this way is contaminated with small quantities of both sodium and sulphate. Ammonium carbonate may be used as precipitating agent, when a purer product is obtained but in poor yield.

(*ii*) The action of carbon dioxide on lithium hydroxide, $2LiOH + CO_2 \rightarrow Li_2CO_3 + H_2O$.

As both reactants are obtainable in a high state of purity, lithium carbonate of very high quality may be prepared by this method.

Lithium carbonate may be purified by utilizing its reverse solubility in water.[1] The small difference in solubility (1·5% approximately at 20°C. and 0·8% approximately at 100°C.) makes the method difficult to apply on anything but a small scale. A reprecipitated lithium carbonate of high quality is obtained. The salt may also be purified by treating an aqueous suspension with carbon dioxide either under pressure or at reduced temperature. A solution of lithium bicarbonate is formed which is decomposed again to carbonate on boiling.

In recent years the greatly increasing interest in lithium compounds has resulted in the development of several new processes for the extraction of lithium as lithium carbonate. In a process used in America[2] crushed spodumene (a lithium aluminium silicate containing approximately 3-5% Li_2O) is heated to 1100°C. in a rotary kiln. At this temperature the change in structure to β-spodumene is almost instantaneous and is accompanied by a breakdown to a form which can be readily milled to a fine powder. The finely milled ore is mixed with concentrated sulphuric acid and heated to 250°C. In this way lithium is replaced by hydrogen in the structure and may be almost quantitatively extracted as lithium sulphate by leaching with water. The leach solution is purified by precipitating magnesium with calcium hydroxide, removing excess calcium with sodium carbonate, and then adding sulphuric acid to pH 7 when iron and aluminium are precipitated by boiling. The pure lithium sulphate solution is then concentrated and lithium carbonate is precipitated with sodium carbonate, washed with water and dried. A yield of approximately 80% and a purity of 98% is claimed. This process is equally applicable to petalite, a lithium aluminium silicate similar to spodumene, found abundantly in Rhodesia.

Two processes,[3,4] similar in detail and designed to extract lithium from amblygonite (lithium aluminium fluoro-phosphate) and from lepidolite (lithium mica) have been patented. The minerals are heated with potassium sulphate or bisulphate and leached with water. A solution containing essentially lithium sulphate and potassium sulphate is obtained by removing elements such as iron, aluminium, calcium and magnesium in a manner similar to that described above. Direct precipitation of this solution gives a recovery of lithium carbonate of 30–60%. The addition of potassium chloride to the solution salts out potassium sulphate, giving a solution of potassium and lithium chloride in which sulphates are relatively insoluble. Lithium carbonate is then precipitated with potassium carbonate. The filtrate, essentially potassium chloride containing dissolved lithium carbonate is reused for the precipitation of subsequent batches of potassium sulphate. A recovery nearly theoretical and a purity of approximately 99% are claimed.

Physical Properties

Spectra.

Lithium carbonate shows strong characteristic absorption bands at the following frequencies:- 1096, 870, 860, 741, 740 and 711 cm.[1,36]

Density.

The accepted figure for the relative density is 2·111. The apparent bulk density of the material is approximately 40lbs./cu.ft. This figure may vary substantially with different methods of formation or precipitation.

Solubility.

The solubility in water has been determined by Haehnel,[5] with the results given in Table I.

TABLE I.- SOLUBILITY OF LITHIUM CARBONATE IN WATER

Temp. °C.	Parts Li_2CO_3/100 parts water
0	1·539
20	1·329
50	1·181
100	0·720

The solubility and solubility product of lithium carbonate are considerably affected by common ions.[6] Addition of lithium chloride has little effect on the solubility product but the solubility falls sharply, while the addition of sodium carbonate has very little effect on the solubility but causes a sharp increase in the solubility product. Both the solubility and the solubility product show the reverse behaviour with respect to temperature that is usual with lithium salts.

Aqueous Systems containing Lithium Carbonate.

The solubility isotherms of the systems Li_2CO_3–Na_2CO_3–H_2O and Li_2CO_3–K_2CO_3–H_2O have been determined at 25°C.[7,8] The isotherm of the first system has two branches, of Li_2CO_3 and of $Na_2CO_3,10H_2O$; similarly the second has two branches, of Li_2CO_3 and of $K_2CO_3,2H_2O$. Contrary to the findings of Lagarde,[6] the effect of the common ion on the repression of combined solubility was found to be normal. No evidence of solid solutions or double salts was found.

Fused Systems containing Lithium Carbonate.

Li || Cl, CO_3, SO_4.

This ternary system has been studied by a visual polythermal method.[9] The liquidus diagram of the system has three fields of crystallisation of the components. The ternary eutectic point is 455°C. with a composition of LiCl 36 mole % and Li_2CO_3 27 mole %. The eutectic of the system Li || Cl, CO_3 was 507°C. with 61 mole % LiCl.

Li, Na || SO_4, CO_3.

The liquidus surface of this system contains[10] a crystallization field of continuous solution of Na_2CO_3 and Na_2SO_4, fields of Li_2SO_4 and Li_2CO_3 and of the compounds $Li_2SO_4,2Na_2SO_4$, Li_2SO_4,Na_2SO_4 and Li_2CO_3,Na_2CO_3. The system has two triple eutectic points.

Li, Rb || F, CO_3.

The liquidus surface of this system consists[11] of the crystallisation fields of the components and the compounds RbF,Rb_2CO_3 and Rb_2CO_3,Li_2CO_3.

The Action of Heat on Lithium Carbonate.

The melting point of lithium carbonate is now reported as 723°C.[12]

The thermal dissociation has been studied using a gold platinum alloy reaction vessel in conjunction with a manometer system,[13] and the results are given in Table II.

TABLE II. - DISSOCIATION PRESSURES OF LITHIUM CARBONATE

Temp. °C.	pCO_2 (mm. Hg)
750	0
800	3·1
850	8·1
900	17·4
950	32·7
1000	56·2
1100	134·4

Above 1100°C. appreciable volatilisation of lithium carbonate occurs. Differential thermal studies show[14] that decomposition begins at approximately 700°C. and is complete at 1310°C. No great accuracy was claimed for these figures owing to difficulties arising from poor thermal diffusion in the apparatus employed. More recently,[12] however, there has been confirmation of the view that decomposition begins at a temperature below 750°C. Using a sample containing 1% of impurity, differential thermal analysis indicated that decomposition commenced at 708°C. Lithium carbonate heated to 950°C. still contained 6·19% CO_2.

Surface Tension.

It has been postulated[15] that if a salt increases the surface tension of water it decreases the solubility of a non-conductor dissolved in the salt solution, and that the reverse is also true. This is verified by the fact that lithium carbonate reduces the solubilities of glycerol, acetone, acetamide, methyl alcohol, acetonitrile and urethane in aqueous solution.

Diffusion.

The diffusion of lithium carbonate in water has been studied by Öholm.[16] Because of its large water envelope the lithium ion has a small diffusion coefficient, following the series:-

$$K^{\cdot} > Na^{\cdot} > Li^{\cdot}$$

Magnetic Susceptibility.

Recent determinations[17] using a modified form of Guoy's balance give the value $-29{\cdot}3 \times 10^{10}$ e.s.u.

Chemical Properties

The general reactions of lithium carbonate to form other lithium salts are well known. The behaviour of this salt in reactions more recently studied is summarised below.

Lithium carbonate dissociates when heated according to the equation:-

$$Li_2CO_3 \rightarrow Li_2O + CO_2$$

The reaction is reported to commence at 708°C.[12] and to be complete at 1310°C.[14] At this temperature lithium carbonate itself is appreciably volatile. If carbon dioxide is continuously removed the conversion to lithium oxide may be readily and completely effected at 1000°C.[18]

Lithium carbonate reacts with carbon dioxide and water to give a bicarbonate solution:-

$$Li_2CO_3 + CO_2 + H_2O \rightarrow 2LiHCO_3$$

The equilibrium constant, K, for the formation of bicarbonate has been determined at 0°C. and 16·5°C.,[19] as follows:- K_0 0·250, $K_{16 5}$ 0·192. The reverse nature of these figures is confirmed by the work of Haehnel[5] who showed the maximum solubility of lithium bicarbonate to be 22·71% at −12°C. under a pressure of 5 atm. of carbon dioxide. Dilute solutions are stable at atmospheric temperature and pressure. The solubility falls progressively with rise in tempature so that at 60°C. a pressure of 50 atm. of carbon dioxide is required to maintain the maximum solubility of 9·61%.

Lithium bicarbonate exists only in solution, lithium carbonate being reformed when the solution is decomposed by heat. The heat of formation in solution from lithium carbonate and carbon dioxide is 1350g.-cal./mol. The heat of solution is 2180g.-cal./mol.[20]

A stable form of lithium bicarbonate is reported to have been isolated,[21] a precipitate stable at 30°C. having been prepared from a solution of lithium bicarbonate containing gelatin by adding alcohol.

The equilibrium between solutions of lithium carbonate at 25°C. and air containing 300–350p.p.m. of carbon dioxide has been studied.[22] The activity coefficients for HCO_3^- (α) and CO_3^{--}(β) given in Table III are determined on the assumption that

$$\frac{d \log \beta}{d \log \alpha} = 4$$

a postulate of the Debye–Hückel theory valid at ionic strengths approaching zero.

TABLE III. - ACTIVITY COEFFICIENTS FOR LITHIUM CARBONATE AND BICARBONATE

Molality	α	β
0	1·000	1·000
0·01	0·896	0·646
0·02	0·862	0·552
0·04	0·819	0·451
0·06	0·790	0·389
0·08	0·767	0·345
0·10	0·747	0·312
0·20	0·683	0·218

Lithium carbonate is decomposed very slowly by boiling water to form the hydroxide.[23] If carbon dioxide is continuously removed from the atmosphere above the solution, it is found that 71% of a 0·27 N. solution decomposes in 10 days.

Lithium carbonate solutions are also hydrolysed to a small extent at room temperature. A four stage mechanism covering the range 0·1 N. to less than 0·0001 N. has been postulated.[24] A solution containing 0·102 moles/l. was progressively diluted to twice its volume with redistilled water, with the following results:-

(*i*) Concentration approximately 0·1 N.

pH (per dilution) 0·05
$(CO_3^{--})_3 + 3H_2O \rightleftharpoons 3CO_3H^- + 3OH^-$
Hydrolysis constant Li $4{\cdot}8 \times 10^{-16}$
Percentage hydrolysis 1–5%.

(ii) Concentration approximately 0·01 N.
pH (per dilution) 0·2
$2CO_3^{--} + 2H_2O \rightleftharpoons (CO_3H^-)_2 + 2OH^-$
Hydrolysis constant Li $1{\cdot}58 \times 10^{-6}$
Percentage hydrolysis 5–12%.

(iii) Concentration approximately 0·001 N.
pH (per dilution) 0·9
$CO_3^{--} + 5Li^+ + H_2O \rightleftharpoons (CO_3Li_5H)^{4+} + OH^-$
Hydrolysis constant Li 8×10^{-8}
Percentage hydrolysis decreases from 12 to 0·2%.

(iv) Concentration approximately 0·0001 N.
pH (per dilution) 0·15
$CO_3^{--} + H_2O \rightleftharpoons CO_3H^- + OH^-$
Hydrolysis constant 4×10^{-10}
Percentage hydrolysis 0·2 to 0·5%.

In many cases lithium carbonate in solid reactions at elevated temperature provides a source of lithium oxide. Its subsequent behaviour is considered under the reactions of lithium oxide.

An equimolecular mixture of lithium carbonate and gallium oxide heated for 4 hr. at 900°C. in an atmosphere of dry hydrogen sulphide[25] and cooled under hydrogen sulphide gives as the product $LiGaS_2$. This compound exists in a light brown rhombic crystalline form, ρ 2·98, m.p. 1020 ± 5°C., and is stable to boiling water.

The action of carbon on lithium carbonate gives carbon monoxide and a lithium carbide of the composition Li_2C_x, which is thought to be lithium carbide dissolved in lithium.[26]

The action of chlorine on lithium carbonate[27] yields lithium chloride at temperatures above 350°C. The reaction proceeds much less readily than with sodium or potassium carbonate and, in contrast to these elements, no perchlorate is formed.

Nascent chlorous acid, prepared by dissolving chlorine dioxide in water, reacts with lithium carbonate solution to give lithium chlorite.[28] A solution of the acid, lithium carbonate and twice the stoicheiometric quantity of hydrogen peroxide is allowed to stand for 5 hr. at 2°C. Lithium chlorate is also formed.

Applications and Uses

The major part of the lithium carbonate produced finds application in the ceramic industry. Many of the properties of ceramic glazes and enamels may be altered advantageously by the addition of small quantities (usually in the range 0–5%) of lithium carbonate to the frits from which they are prepared. These advantageous modifications include the lowering of the temperature of vitrification,[29] of the temperature of softening, and of the coefficient of thermal expansion, and improving the gloss and the wetting characteristics of the molten glaze.[30]

A minor ceramic application is found in the production of dielectric materials. Bodies with very low dielectric loss factors are prepared by adding very small quantities of lithium carbonate to the standard materials.[31]

Lithium carbonate has been found to give satisfactory results as a catalyst in the decomposition of hydrocarbon oils with steam. A mixture of oil and steam passed through the catalyst bed is converted to a combustible gas containing large quantities of methane, hydrogen and carbon monoxide.[32]

A further small application of lithium carbonate is in the preparation of phosphors, in which increased luminescence may be achieved by activation with small quantities of lithium carbonate. Phosphors based on strontium sulphide, strontium hydroxide and calcium carbonate are specifically mentioned.[33,34]

Cements with relatively high alkali content when mixed with rock aggregate to form concrete, react and expand. In the course of time this reaction leads to a deterioration in the concrete strength owing to cracking. Lithium carbonate has been found to be most effective in reducing this expansion, when added in the proportion of 1% of the cement.[35]

Analytical

The possible use of lithium carbonate as a flux in spectrochemical analysis has been proposed,[37] the sample, diluted nine times with lithium carbonate, being burned to completion between graphite electrodes. High accuracy has not so far been achieved.

In determining the isotopic composition of lithium, samples of lithium carbonate of unknown isotopic composition and a standard sample are placed on a photographic plate and irradiated with neutrons.[38] After development the plate is evaluated photometrically.

SECTION XVII

LITHIUM NITRATE

By G. SCHOLES

The crystal structure of lithium nitrate has been examined by X-ray methods[1] and found to have the following parameters: $r = 5{\cdot}74 \pm 0{\cdot}02$ A, $\alpha = 48°3' \pm 10'$, $d = 2{\cdot}38$, $u = 0{\cdot}264 \pm 0{\cdot}006$. The crystals are isomorphous with sodium nitrate.

Lithium nitrate melts[2] at 251·4°. Davis, Rogers and Ubbelohde have suggested[3] that the low melting points of Group I nitrates, as compared with those of the corresponding halides, are due to the formation of association complexes in the nitrate melts. From a survey of published data on the electrical conductances and viscosities of lithium nitrate melts, these authors have derived values of the activation energies for ionic conductance (E_σ) and for viscous flow (E_η), using the relationships:

$$\ln\sigma = \sigma_0 - \frac{E_\sigma}{RT} \quad \text{and} \quad \ln\eta = \eta_0 - \frac{E_\eta}{RT}$$

Table I shows the values obtained over various temperature ranges.

TABLE I.- ACTIVATION ENERGIES FOR IONIC CONDUCTANCE (E_σ) AND FOR VISCOUS FLOW (E_η) IN LITHIUM NITRATE MELTS

Temp. range (°C.)	E_σ (kg.-cal./mol.)	σ_0	Temp. range (°C.)	E_η (kg.-cal./mol.)	$10^4\eta_0$
270–290	4·49	55·4	260–354	4·23	11·90
400–440	2·83	3·3	354–429	6·91	1·38

The coefficient of internal fraction of the fused salt (η') has been measured at different temperatures over the range 260° to 429°.[4] The experimental results fall on a curve which can be represented by the equation $\eta' = A + Bt + Ct^2 + Dt^3$, where t is the temperature, $A = 0{\cdot}31896$, $B = -1{\cdot}754 \times 10^{-3}$, $C = 3{\cdot}831 \times 10^{6}$ and $D = -3{\cdot}23 \times 10^{9}$.

Compound formation involving lithium nitrate has been observed in only a few systems and the relevant information is recorded in Table II.

TABLE II.- MOLECULAR COMPOUNDS CONTAINING LITHIUM NITRATE

System	Compound formed	Reference
$LiNO_3$-$RbNO_3$	$LiNO_3, RbNO_3$ m.p. 191°	5, 6
$LiNO_3$-$LiOH$	$LiNO_3, LiOH$ decomposes at 195°	7
$LiNO_3$-$CO(NH_2)_2$	$LiNO_3, 2CO(NH_2)_2$ m.p. 126°	8

Several other binary and ternary systems containing lithium nitrate have been investigated; data are available for the following:

	Reference
$LiNO_3$–$Cd(NO_3)_2$–$NaNO_3$	9

	Reference

$LiNO_3$–$TlNO_3$	21,22
$LiNO_3$–KNO_3–$TlNO_3$	22
$LiNO_3$–K_2SO_4–KNO_3	22
$LiNO_3$–$Sr(NO_3)_2$	23
$LiNO_3$–$NaNO_2$–KNO_2	24
$LiNO_3$–$Pb(NO_3)_2$–H_2O	25,26
$LiNO_3$–NH_4NO_3–H_2O	11

Some thermochemical data for lithium nitrate, in the solid state as well as in solution, have been reviewed by Bichowsky and Rossini.[27] The heat of formation of the salt from its elements is given as 115·352kg.-cal. and the heat of solution in water S_{200} = 0·333kg.-cal.

The transition of the trihydrate, attributed to the reaction $LiNO_3,3H_2O \rightarrow LiNO_3,\frac{1}{2}H_2O + 2\frac{1}{2}H_2O$, (Mellor, II, 815) has been studied in alcohol[28] and also in pyridine, acetone and amyl alcohol.[29] The transition point, calculated from electrolytic resistance-temperature data, was found to be independent of the nature of the solvent and, within the accuracy of the experiments, the same as the value found in water (29·6°). Some doubt has been cast on the existence of the hemihydrate.[11] In the system $LiNO_3$–NH_4NO_3–H_2O this particular hydrate does not appear to exist as a stable solid phase. A direct investigation of the transition point in the $LiNO_3$–H_2O system, using the dilatometer technique, failed to reveal the transition $LiNO_3,\frac{1}{2}H_2O \rightarrow LiNO_3 + \frac{1}{2}H_2O$, which is said to occur at 61·1°.

The solubility of lithium nitrate in several organic solvents has been determined[30] with results given in Table III. It has been shown[31] that lithium nitrate is much less soluble in hydrogen peroxide than in water; definite discontinuities in the curve for mole fraction of hydrogen peroxide in the solvent versus molality of the salt indicate the appearance of new solid solvate phases separating from the water-rich solvents.

TABLE III.- SOLUBILITY OF LITHIUM NITRATE IN ORGANIC SOLVENTS

Solvent	Solubility (g./100c.c. solvent)	
	At 0°	At 25°
iso Amyl alcohol	5·41	9·5
Acetonitrile	-	2·99
Pyridine	27·4	37·15

The vapour pressures of aqueous solutions at 25° have been determined over a wide concentration range, from 0·1N. to saturation.[32,33] Vapour pressure data have been used for the calculation of the chemical potential of lithium nitrate in aqueous solution[34] and also to obtain values for the mean activity and osmotic coefficients of the ions.[33,35] The results are given in Table IV.

The diffusion coefficients of fairly concentrated aqueous lithium nitrate solutions, given in Table V, indicate that ion-pair formation occurs to only a small extent.[36]

TABLE IV.- ACTIVITY AND OSMOTIC COEFFICIENTS OF LITHIUM NITRATE IN AQUEOUS SOLUTION[35]

Concentration (Molar)	Activity coefficient γ	Osmotic coefficient ϕ
0·1	0·788	0·938
0·5	0·726	0·954
1·0	0·743	0·997
2·5	0·896	1·134
5·0	1·310	1·352
10·0	2·455	1·637
13·5	3·398	1·754

TABLE V.- DIFFUSION COEFFICIENTS OF AQUEOUS LITHIUM NITRATE SOLUTIONS AT 25°

Concentration (Molar)	Diffusion coefficient ($cm.^2$ $sec.^{-1} \times 10^{-5}$)
0·1	1·240
0·5	1·260
1·0	1·293
2·5	1·336
5·0	1·238

The electrical conductivities of solutions of lithium nitrate in various solvents have been investigated. With 0·0001 to 0·002N. solutions in pure ethanol, the decrease in conductivity is proportional to the square root of the equivalent concentration.[37] Conductivity and also viscosity measurements have been carried out in several binary alcoholic systems, at 25°, using lithium nitrate concentrations varying from 0·1 to 0·00625M.[38,39] These particular systems were as follows: methanol–water, methanol–ethanol, ethanol–water, *n*-propyl alcohol–water, *iso*propyl alcohol–water, ethanol-*n*-propyl alcohol, ethanol–*iso*propyl alcohol and *n*-propyl alcohol–*iso*propyl alcohol. In all systems containing water a maximum was found in the viscosity–composition curve. Only one system, viz. methanol–water, exhibited a minimum in the conductivity–composition curve. In solvents containing only alcohols no maxima or minima were observed in either the viscosity or conductivity–composition curves.

Klochko and Grigor'ev[40,41] have compared the conductivities and viscosities of solutions of lithium nitrate in water at various temperatures with the corresponding properties of solutions of the salt in methanol. It was found that, generally, the property curves of lithium nitrate in methanol resembled closely the analogous curves in water, except for the numerical values. At 25°, the conductivity maximum in water coincided with 10·3mol.-% of lithium nitrate and in methanol with 8·2mol.-%. The absolute values of the conductivities at 25° and at 50° in water were 5·8 to 5·9 times the corresponding values in methanol, whereas the viscosities in methanol were only 1·34 to 0·35 times the corresponding values in water. Apparently, the interaction of the components in the two systems is quite different. Table VI gives some data[42] for the conductivity and viscosity, at 25°, for comparative concentration of $LiNO_3$ in water, in methanol and in water-dioxan (1:1). Qualitatively, the decrease in conductivity on going from water to dioxan–water mixtures can be explained by a decrease in the dielectric constants and a decrease in the dipole moments of the three solvents.

Refs. p. 261

TABLE VI.- ELECTRICAL CONDUCTIVITY AND VISCOSITY OF SOME SOLUTIONS OF LITHIUM NITRATE IN VARIOUS SOLVENTS

Solvent	Concentration (mol.-%)	Conductivity (ohm^{-1} cm.$^{-1}$)	Viscosity (centipoise)
Water	8·91	0·1629	1·487
Methanol	9·09	0·0290	2·067
Dioxan	8·81	0·00485	2·704

Electrokinetic potentials of aqueous lithium nitrate solutions have been determined using concentrations up to 0·01N.[43,44]

Some figures are available[45] for the surface tension of solutions of lithium nitrate (5% to 15%) in water and also in 10%-, 20%- and 30%-acetone/water mixtures at 20° and at 40°.

Lithium nitrate is very soluble in liquid ammonia[46,47] and Table VII gives some values at selected temperatures. The solubility curves indicate the formtion of the compounds $LiNO_3,8NH_3$, $LiNO_3,4NH_3$ and $LiNO_3,2NH_3$ in the temperature intervals −81° to −52°, −52° to 8° and −8° to 12·5° respectively. At ordinary temperatures, saturated solutions of the salt in liquid ammonia have moderate vapour pressures[48] (see Table VIII) and this has aroused interest in the use of this system in refrigerators.[49-51]

TABLE VII.- THE SOLUBILITY OF LITHIUM NITRATE IN LIQUID AMMONIA

Temp. °C.	Solubility (wt. %)
−77·7	0
−54·0	35·66
−28·5	40·51
5·5	44·28
42·0	71·59
160	82·60
264	100

TABLE VIII.- VAPOUR PRESSURE OF AMMONIA OVER SATURATED SOLUTIONS OF LITHIUM NITRATE IN LIQUID AMMONIA

Temp. °C.	V.p.(mm. Hg)
10	102
20	155
30	230
50	455

Other physicochemical properties of the lithium nitrate–liquid ammonia system which are available[47] include the specific gravity of solutions at 20° and and the electrical conductivity of saturated solutions in the temperature range −33° to 20°. It has also been shown[47] that the decomposition potential of the nitrate in liquid ammonia falls from 5·2V. at −40° to 4·0V. at 25°. The molar heat of the salt in liquid ammonia at −33·4° is 10·8kg.-cal.[52]

Lithium nitrate dissociates above its melting point according to the equation $2LiNO_3 \rightleftharpoons 2LiNO_2 + O_2$, the reaction being reversible. Under conditions of standard pressure it has been found[53] that the temperature of dissociation is 474·1°. From determinations of the temperatures of dissociation at a series of pressures the heat of dissociation has been calculated as −25·09kg.-cal.[54]

The products of the reduction of lithium nitrate trihydrate, $LiNO_3,3H_2O$, by hydrogen in a silent discharge are lithium hydroxide, lithium nitrite, ammonia and nitrogen dioxide.[55] Photochemical reduction of the anhydrous salt to nitrite and oxygen by light from a high pressure mercury arc has a quantum yield of approximately 0·002 and the rate of photolysis is little affected by temperature in the range 30°–200°.[56]

Lithium nitrate reacts with monosodium dioxide, NaO_2, in liquid ammonia to form solid products containing fairly large proportions of lithium peroxide. The nitrate does not react with monopotassium dioxide under these conditions.[57]

When solutions of lithium nitrate in acetone are passed through an ion-exchange column (Dowex A1) the salt is highly absorbed.[58] This absorption is not an ionic exchange and it has been suggested that it is due to the presence, in the absorbed state, of the complex $[Li(NO_3)_2]^-$.

The etching effect of molten lithium nitrate on glass has been examined.[59] It is found that glasses treated in this manner readily break and that the method cannot be used in practice. It seems that the glass undergoes a chemical change; the sodium in it is replaced by lithium, the structure is loosened and the expansion coefficient is thus changed.

SECTION XVIII

LITHIUM PHOSPHATE

By L. PRATT

The ternary system $Li_2O-P_2O_5-H_2O$ has been studied at 0°C. and 20°C.;[1,2,3] the dilithium salt Li_2HPO_4 was not formed under the conditions studied. Neither Li_3PO_4 or LiH_2PO_4 is hydrated. The neutral phosphate, Li_3PO_4, cannot be prepared in a pure state either by exact neutralisation of orthophosphoric acid by lithium hydroxide or by metathesis between an alkali phosphate and a neutral lithium salt.[5] The neutralisation method gives a precipitate having the composition of a hemihydrate, $Li_3PO_4,0{\cdot}5H_2O$, and since the water is removed only at red heat it is possible that the compound is really the salt $Li_6H_2P_2O_9$ of the acid $H_8P_2O_9$. Complete neutralisation of orthophosphoric acid by lithium hydroxide at 100°C. is said to give lithium hydroxyapatite, $3Li_3PO_4,LiOH$.[5] The neutral phosphate is produced together with phosphine, when lithium hydroxide is heated with red phosphorus.[6] The dihydrate, $Li_3PO_4,2H_2O$, is produced if the salt prepared by adding phosphoric acid to an excess of lithium hydroxide solution is dried at about 16°C. The dihydrate is converted to the hemihydrate by drying at 60°C. for several days.[16] The solubility in water of Li_3PO_4 is given as $0{\cdot}022 \pm 0{\cdot}001\%$ at 0°C. and $0{\cdot}03 \pm 0{\cdot}002\%$ at 20°C.;[1] the compound is too soluble to be used in the gravimetric determination of lithium.[8] In another attempt to determine the solubility it was found that when the salt was in contact with water at a constant temperature for several days a colloidal suspension was produced which could not be filtered off; however, the specific conductivity of the saturated solution at 25°C. was found to be $9{\cdot}37 \times 10^{-4} ohm^{-1} cm^{-1}$ (corrected for the conductivity of water) and from this result the solubility at 25°C. was calculated to be 0·297g./l.[16]

The crystallographic unit cell dimensions of Li_3PO_4 are a = 4·86A., b = 10·26A., and c = 6·07A., the lithium ions probably occupying three quarters of the octahedral holes between the close-packed oxygen atoms.[7] This salt has been used as a flux to dissolve contaminating metal oxides during the coating of iron wire with copper-nickel alloys.[9]

The mono- and dilithium phosphates, LiH_2PO_4 and Li_2HPO_4, are said to be produced by acidifying the neutral salt.[10] Monolithium phosphate undergoes thermal dissociation between 160° and 260°C. to give the hydropyrophosphate, $Li_2H_2P_2O_7$, which itself dissociates between 260° and 400°C. to give the metaphosphate, $LiPO_3$. The activation energies for the two dissociations are given as 12 and 15kg.-cal./mole respectively.[11] The dielectric constant of LiH_2PO_4 at 9500mcs./sec. has been measured between 50° and 300°C.,[12] but no discontinuous change corresponding to a phase transition was observed. The monolithium salt has a solubility in water of $55{\cdot}8 \pm 0{\cdot}1\%$ at 0°C.[1]

Lithium salts of polymeric condensed phosphates are less dissociated in solution than those of the other alkali metals.[13] Solid melts of lithium polyphosphates have glass-like properties.[4] A 1% solution of lithium pyrophosphate, $Li_4P_2O_7$, is hydrolysed only slowly to the neutral orthophosphate.[14] Lithium tetraphosphate, $Li_6[P_4O_{13}]$, has not been obtained in a crystalline state although it is known in solution.[15]

SECTION XIX

THE SPECTROSCOPY OF LITHIUM AND CERTAIN OF ITS COMPOUNDS

By R. F. BARROW and LADY ANNE THORNE

THE SPECTRUM OF ATOMIC LITHIUM

By A. THORNE

Introduction

The spectrum of atomic lithium has been much investigated since the early days of spectroscopy, and indeed the study of the alkali metal spectra played an important part in the development of modern spectroscopic theory. Brief historical accounts with references are given in most of the standard text-books on spectroscopy,[1-3] and some review articles.[16,17]

A description of the lithium spectrum and its explanation in terms of modern theory are to be found in relevant text-books.[1-6] The neutral lithium atom has the ground state electron configuration $1s^2\ 2s\ {}^2S_{1/2}$, and so Li I has a doublet spectrum. The first doublet of the principal series, corresponding to the transition $2s\ {}^2S_{1/2}-2p\ {}^2P_{1/2,3/2}$, is at 6708 A., and the rest of the principal series is in the ultra-violet region. The sharp and diffuse series lie in the visible and near ultra-violet regions, and the fundamental series in the infra-red. The most important energy levels and transitions of Li I are shown diagrammatically by Grotrian.[7] Li II is a helium-like ion with the ground state $1s^2\ {}^1S_0$, and Li III is of course a one-electron hydrogen-like ion. Numerical values of the energy levels of Li I, II, and III found experimentally have been tabulated by Bacher and Goudsmit,[8] and more recently and more comprehensively by the National Bureau of Standards.[9]

The first tabulations of line series were given by Fowler[10] and Paschen and Götze[11] for Li I. Later tables compiled by Moore[12,13] give many multiplets of Li I and II from 13,000 A. to the far ultra-violet, together with a finding list arranged by wave-length. The M.I.T. wave-length tables,[14] which list the arc and spark lines of all elements between 10,000 A. and 2,000 A. in order of wave-length, include a list of the 'raies ultimes'; these are also given in the Vatican Observatory 'Atlas of Persistent Spectra'.[15]

In 1938 Shenstone[16] published a summary of spectroscopic work on the arc and spark spectra of all elements, incorporating tables showing how thoroughly each spectrum had been investigated. Meggers[17] brought the information up to date in 1946. At the same time Hartree[18] presented in a similar way a summary of the valculations on atomic wave-functions, of which a large number have been made on the relatively simple two- and three-electron atoms represented by Li^+ and Li.

Astrophysics.

Lithium spectral lines of astrophysical interest are listed in Moore's multiplet tables.[12,13] The resonance lines 6708 A. have been identified in the solar spectrum,[19-21] where they appear to be less intense in the disc than in spot spectra.[19,20] Compared to other metals, lithium is much scarcer in the sun than on the earth.[21]

The resonance lines of lithium have also been found in absorption in a few stellar spectra.[22-26]

Excitation

The spectrum of lithium has been excited in flames, arcs, sparks, and various forms of discharge and also observed by several methods in absorption. In this sub-section reference is made only to those papers in which the conditions or mechanism of excitation has been the main consideration. Wavelength and intensity measurements of spectral lines and accounts of specialised sources for particular investigations are described in later sub-sections; in particular, references to various forms of spark source are given in the sub-section on ionised lithium (see page 269).

Flames, Furnaces and Collision Processes.

Many investigations have been made of the relation between the intensity of the spectral lines emitted by lithium atoms in various sorts of flame and the concentration of the lithium salts.[1-5,36] This relation has been generally shown to follow a linear law at low concentrations and a square-root law at higher concentrations. Different methods of introducing the salt into the flame have been described.[1,5,6] The distribution in the flame of the excited atoms,[7,36] the effect of adding salts of other alkalies,[8,9] and photoluminescence in flames[13] have all been studied.

Both emission and absorption spectra have been examined in the electric furnace and in exploding wires.[10-12]

The reversal temperature of the red resonance line of lithium (*i.e.*, the brightness temperature of a continuous background against which it just vanishes) has been used to measure flame temperatures[14] and the advantages and limitations of the method have been discussed.[15]

Lines of the lithium spectrum have been excited by collisions with hydrogen and helium atoms.[16] They have also been identified in the luminous trails of ultraspeed pellets containing lithium.[39]

Refs. p. 267

Arcs.

The emission of lithium lines in arc sources has been studied with reference to their spatial distribution, luminous duration, voltage dependence, etc.[17-20] Reversal with increasing concentration has been noted.[21] The effect of adding varying amounts of other alkalies has been investigated with particular reference to methods of quantitative analysis.[20,22] Running the arc in an atmosphere of argon has been found to favour excitation of the spark spectrum.[38]

Discharges.

The emission of the lithium spectrum from anode rays has been studied in some detail.[23-29] Relative intensities of the alkali metal spectra in discharges passed through amalgams have been measured.[30,31] The Li I and Li II spectra have been studied in the negative glow[32,33] and the Li I spectrum in electrodeless discharges.[34,35] The hollow-cathode discharge has been used as a source in determining the ^{6}Li:^{7}Li abundance ratio by spectroscopic methods.[37]

The Spectrum of Neutral Lithium

The neutral lithium atom has the ground-state configuration $1s^2\ 2s\ ^2S_{1/2}$, with an ionisation potential of 5·390 V., corresponding to a term value for the ground state of 43,487·19 ± 0·02 cm.$^{-1}$, or a wave-length limit of 2298·814 A. for the principal series.[1]

The results of early work are summarised in Fowler's tables,[4] which include the first 41 members of the principal series, a few each of the sharp and diffuse, and several forbidden lines. Some additions and corrections were made subsequently,[5,6,8-10] and the narrow doublet splittings of the lowest ^{2}P and the first few ^{2}D levels were resolved.[7,8] The lower members of all series are listed in Moore's multiplet tables.[2,3] The energy levels derived from all these sources are listed in full in the National Bureau of Standards 'Atomic Energy Levels', published in 1949.[1] Term values are given for all excited states of the $2s$ electron up to $11s$, $42p$, $12d$ and $5f$ respectively. The first four members of both the sharp and diffuse series have been very accurately measured interferometrically by Meissner *et al.*[8] (Certain values for the D-levels quoted in the 1948 edition of 'Atomic Energy Levels' have been subsequently corrected.[9,10])

The doublet splitting in all levels is extremely narrow. Table I gives the values, measured interferometrically, for the 2 ^{2}P and the 3,4,5,6 ^{2}D levels of ^{7}Li; the ^{2}D levels, unlike those of the heavier alkali metals, are not inverted.

TABLE I. - DOUBLET INTERVALS IN THE SPECTRUM OF Li I.

n	2	3	4	5	6
$\Delta\nu(n^2P)$ (cm.$^{-1}$)	0·3366[8] 0·3372[7]	–	–	–	–
$\Delta\nu(n^2D)$ (cm.$^{-1}$)	–	0·037	0·015	0·010	0·005

The value found for the 2 ^{2}P splitting of ^{6}Li is 0·317 cm.$^{-1}$.[7] The question of isotope shifts between lines of the two isotopes is discussed later (see page 272).

Forbidden lines of the $2s$–nd[11,13] and $2p$–np[14-17] series have been found and their intensities measured. In the $2s$–nd series the intensities have been found to agree with those calculated for quadrupole transitions.[12] The appearance of forbidden lines in an external electric field is referred to under Stark effect (see page 271). Two review articles on forbidden lines contain references to the spectra of the alkali metals.[18,19]

The continuous absorption (photoionisation) spectrum of lithium has been investigated in the region 2300 A. to 1850 A.[26,27] The cross-section is found to be $2{\cdot}5 \times 10^{-18}$ cm.^{2} at the series limit and to fall off approximately as $\lambda^{3\cdot5}$ below this. Ditchburn *et al.*[28] have compared theoretical and experimental cross-sections for all the alkali metals.

A general account of the experimental determination of line transition probabilities has been given by Mitchell and Zemansky.[29] Measurements on the principal series have been made by direct determination of the lifetime of the excited state[20,21] and by total absorption[22-25] and anomalous dispersion[26] methods. The latest value[25] for the f-value of the resonance line is 0·72 ± 0·03, corresponding to a lifetime of 2·8 × 10 sec. for the excited 2 ^{2}P state.

Calculations of intensities in both the line spectrum and the continuum are referred to later (see page 275).

The Spectrum of Ionised Lithium

Singly ionised.

Lines of the Li II spectrum were early found in discharge tubes[4-6] and in anode rays,[7-10] and their conditions of excitation were studied in various forms of spark and condensed discharge.[11-16] The spectrum was analysed by Schüler[17] and Werner,[18-20] and was shortly afterwards extended farther into the vacuum ultra-violet region by Edlén and others.[21-24] The measured wave-lengths, classifications, and intensities of several of these lines, as far down as 171 A., are also to be found in Moore's multiplet tables.[2,3]

Li II has a helium-like spectrum with the ground-state electron configuration $1s^2\ {}^1S_0$. The ionisation potential is 75·6193 ± 0·0031 V., corresponding to a ground term value of 610,079 ± 25 cm.$^{-1}$.[1] The 43 terms listed in the National Bureau of Standards 'Atomic Energy Levels'[1] incorporate the results of the above-mentioned analyses[17-24] and cover the electron configurations $1s^2$; $1s\ 2\text{-}7s$; $1s\ 2\text{-}6p$; $1s\ 3\text{-}8d$; and $1s\ 4\text{-}8f$.

The fine structure of the $1s\ 2p\ {}^3P_{0,1,2}$ term has been examined in detail in the course of hyperfine structure measurements (see page 272).

Doubly ionised.

Li III is a hydrogen-like ion, in whose spectrum the first members of the 'Lyman' series (ground state $n = 1$) and the 'Balmer' series (ground state $n = 2$) have been measured.[25,26] 'Atomic Energy Levels'[1] gives the terms derived from these measurements for values of the principal quantum number up to $n = 7$, the fine structure being resolved up to $n = 5$. The ionisation potential for the ^{6}Li isotope is 122·419 V. and for the ^{7}Li isotope 122·420 V., corresponding to term values of the $^2S_{1/2}$ ground state of 987,644·9 cm.$^{-1}$ and 987,657·8 cm.$^{-1}$ respectively.[1]

Zeeman, Stark, and Pressure Effects

Zeeman Effect.

The Zeeman effect in the alkali metal doublets is described in text-books on spectroscopy (see page 265). Rather fuller accounts have been given by Back and Landé.[1,2] As the historical resumés in these references indicate, the 'anomalous' Zeeman patterns of the resonance lines of the alkali metals played an important part in the development of spectroscopic theory.

The Landé *g*-factor for the $^2S_{1/2}$ ground state of lithium is 2, and for the $^2P_{1/2}$, $^2P_{3/2}$ levels it is 2/3, 4/3, respectively. In a magnetic field not strong enough to break down the spin-orbit coupling, the Zeeman pattern, in terms of the classical Lorentz splitting $\Delta\nu_L$, consists for the $^2S_{1/2}-{}^2P_{1/2}$ line of two π-components at $\pm\frac{2}{3}\Delta\nu_L$ and two σ-components at $\pm\frac{4}{3}\Delta\nu_L$, and for the $^2S_{1/2}-{}^2P_{3/2}$ line of two π-components at $\pm\frac{1}{3}\Delta\nu_L$ and four σ-components at $\pm\frac{2}{3}\Delta\nu_L$, $\pm\frac{5}{3}\Delta\nu_L$. As the magnetic field becomes strong enough to break down the spin-orbit coupling, the components of both lines merge and tend towards the Paschen-Back pattern, consisting solely of a π-component in the position of the field-free line and σ-components at $\pm\Delta\nu_L$. The Zeeman effect in the alkali metals has been treated mathematically on the basis of Dirac's theory.[8] In lithium the pattern has actually been observed all the way from zero to the strong field case,[3] which is reached, owing to the narrowness of the doublet splitting in lithium, at the relatively low value of about 34,000 gauss. Multiplet structure in the Paschen–Back triplet due to the residual spin-orbit coupling has been resolved and found to agree with the results of calculations.[4-7]

The Zeeman effect in the ground state of lithium has been studied in atomic beam magnetic resonance experiments (see page 273), in the course of which extremely accurate measurements of the splitting have been made. The $g(^2S_{1/2})$ values for lithium, sodium and potassium are found to agree to 1: 40,000.[24] Reasons for small discrepancies have been suggested.[25]

Stark Effect.

The Stark effect is rather briefly discussed in most text-books. A fuller account has been given by Minkowski.[9] The Stark pattern is considerably more complicated than the Zeeman pattern. In the alkali metals the first-order effect is a quadratic one: an asymmetric splitting proportional to the square of the field strength. When unresolved this appears as a simultaneous broadening and shift of the line. The theory has been discussed in several papers.[18-21]

The broadening and shift found in early work on lithium lines was in good agreement with the calculated values.[10-14] In a few experiments the Stark components have actually been resolved.[15-17]

The effect of electric fields on the intensities of forbidden lines in the lithium spectrum has been examined.[22,23]

Pressure Effects.

A general account of the effects of pressure on spectral lines is given by Mitchell and Zemansky,[28] and in 1957 a review article was published by Ch'en and Takeo[29] giving many references to both experimental and theoretical papers on the subject. Some of the most extensive research has been done on the alkali metals, but little of this refers to lithium. In early experiments the broadening of lithium lines in high vapour densities of lithium vapour was compared with the effect to be expected from inter-molecular Stark broadening.[10,12] More recent experiments with high vapour densities have indicated the presence of bands near the series lines in both emission[26] and absorption;[27] these have been ascribed to loosely-bound polarization molecules of Li_2.[27,29]

Hyperfine Structure and Nuclear Moments

Before the development of magnetic resonance techniques nuclear moments were determined primarily by optical investigation of the hyperfine structure (hereafter referred to as hfs). The theory is given in Kopfermann's book,[1] which also describes the methods used in both optical and radio-frequency spectroscopy. The methods of obtaining nuclear moments are also summarised by Ramsey,[2] with tables of results up to 1952 and many references. Nuclear effects in atomic spectra[34] and the role of nuclear moments in the shell model of the nucleus[36] have recently been reviewed. The data for the lithium isotopes, as quoted by Ramsey,[2] are summarised in Table II. The columns headed $\Delta\nu(2^2S_{1/2})$ refer to the splitting between the two hyperfine levels of the $2^2S_{1/2}$ ground state; this has been measured much more accurately by radio-frequency methods than is possible optically[35] (as has the magnetic moment), but the first few figures of the value converted to cm.$^{-1}$ are given here for convenience. I is the nuclear spin, μ the nuclear magnetic moment (in nuclear magnetons) and Q the nuclear electric quadrupole moment.

TABLE II. - NUCLEAR MOMENTS OF THE LITHIUM ISOTOPES

	I	μ (n.m.)	Q	$\Delta\nu(2^2S_{1/2})$	
				mc/s	cm.$^{-1}$
^{6}Li	1	0·82189 ±0·00004	–	228·208 ± 0·005	0·0076
^{7}Li	$3/2$	3·25586 ±0·00011	–	803·512 ± 0·015	0·0268

Optical hyperfine structure in the lithium spectrum is complicated by the isotope shift between components of the two stable isotopes, ^{6}Li and ^{7}Li, and by the narrowness of the fine structure doublet splitting. In the resonance line at 6708 A., for example, the isotope shift and the doublet splitting of the 2^2P level are both of order 0·3 cm.$^{-1}$, while the hyperfine structure (hfs) splitting in the $2^2S_{1/2}$ level is smaller by a factor of about 10. The isotope shift was therefore investigated before the hfs proper, and was indeed first observed by McLennan and Ainslie[4] in 1922 in the resonance line. Their interpretation of the effect was questioned[5-8] until, after further experiments,[9,10] measurements with greater resolution could be made.[11-16] The strong component of the ^{6}Li doublet, however, lies so close to the weak component of the ^{7}Li doublet that the two were not finally resolved until the line was examined in an atomic beam source to reduce the Doppler width; the shifts then found were +0·345 cm.$^{-1}$ and +0·36 cm.$^{-1}$ for ^{7}Li relative to ^{6}Li in the $2^2S_{1/2}-2^2P_{1/2}$ and $2^2S_{1/2}-2^2P_{3/2}$ lines, respectively.[31,32] General accounts of the isotope effect in atomic spectra have been given,[1,34] and Hughes and Eckart[3] have made quantum mechanical calculations for the effect in Li I and II. In very recent measurements with separated isotopes the shift has been measured in a large number of lines besides the resonance line and considerable discrepancies found with the calculations.[37,53]

The isotope shift in the resonance line has been used in spectro-isotopic assays to measure the relative abundance of the lithium isotopes.[17,18]

Hfs was first studied in the $2^3P_{0,1,2}-2^3S_1$ transition of Li II at 5485 A., where the splitting is greater than in the resonance line of Li I. Since

Refs. p. 273

multiplet splitting, hfs, and isotope shift are all of the same order of magnitude, however, the pattern is a complicated one, in which Schüler resolved 14 components.[19-21] Patterns calculated for various nuclear spin values[22-25] agreed best with the observed structure for $I = 3/2$, $\mu = 3{\cdot}29$ n.m. Further experimental work[26-28] confirmed this assignment.[29] Originally no hfs was found in the ^{6}Li components,[21] but Schüler[28] later found unresolved structure from which he deduced $\mu = +0{\cdot}6 \pm 0{\cdot}2$ n.m. assuming $I = 1$. This early work on the nuclear moments of lithium has been reviewed.[30]

In the resonance line the hfs is due to the splitting into two levels of the $2^{2}S_{1/2}$ ground state, for the $2^{2}P$ splittings are too narrow for resolution, although they can be deduced from displacements. The $2^{2}S_{1/2}$ splitting was first resolved by Jackson and Kuhn,[31] using an atomic beam source in absorption, and found to be 0·0275 cm.$^{-1}$, in good agreement with the value later found by Meissner *et al.*[32] with an atomic beam in emission, and also with the magnetic resonance value found since.[2] The values deduced from these two experiments for the $2^{2}P_{1/2}$ splitting are respectively[31] $0{\cdot}0015 \pm 0{\cdot}0009$ cm.$^{-1}$ and[32] $0{\cdot}007 \pm 0{\cdot}002$ cm.$^{-1}$ In the first of these experiments the hfs of the Zeeman effect was also resolved.[31] The later work on optical hfs in all the alkalies and on the hfs of the Zeeman effect has been reviewed.[31,33]

The most accurate measurements of nuclear moments and of the hfs and Zeeman levels of the ground state have been made by radio-frequency methods, mostly in atomic and molecular beams,[1,2,35] although very precise measurements of the magnetic moments have been made in the solid state by nuclear magnetic resonance techniques.[43-46] The spin and magnetic moment of both lithium isotopes were early found by the atomic beam method of zero moments.[38,39] Later, Rabi's magnetic resonance technique was applied to molecular beams of lithium to measure the nuclear magnetic moments with greater accuracy[40] and to atomic beams to measure the ground state hfs and Zeeman effect in both isotopes.[41,42] The ratio of the nuclear g-values in the two isotopes has been very accurately measured by the same method and the result ($g_7{:}g_6 = 2{\cdot}64094 \pm 0{\cdot}00005$) compared with theoretical estimates.[47]

Since the hfs of the $^{2}P_{3/2}$ state has not yet been resolved, the absolute value of the nuclear electric quadrupole moment is not known for either isotope, although the ratio $Q_6{:}Q_7$ has been found to be from[51] $2{\cdot}3 \times 10^{-2}$ to[50] $1{\cdot}9 \times 10^{-2}$, the sign of Q being the same for both isotopes.[49] Ramsey quotes in his tables[2] a value calculated by Kusch from molecular beam experiments,[48] but a later paper[52] throws considerable doubt on this calculation, which is therefore not included in Table II above.

Calculations

Before the development of quantum mechanics, energy levels and doublet splittings in the lithium spectrum were estimated from iso-electronic sequences[1,2] and semi-empirical formulæ[3,4] for both Li I and Li II. Semi-empirical formulæ for certain energy levels and quantum defects have also been given recently.[5-7]

A qualitative quantum-mechanical representation of the two-electron system of Li II was first given by Heisenberg.[8] A full account of the determination of atomic energy levels and eigenfunctions (and hence transition probabilities) is to be found in the book of Condon and Shortley.[9] Hartree in 1946 [10] summarised the calculations carried out up to that date on many spectra, including those of lithium from Li^- to Li III. The two- and three-electron spectra of Li I and Li II, being the simplest non-hydrogenic spectra, are of particular interest, and a correspondingly large number of calculations has been made on them. The scope of these is indicated briefly here.

Solutions of the Hartree self-consistent field equations with exchange terms were first given for Li I by Fok and Petrashen.[11] Analytic functions both without[12,13] and with[16,17] exchange have been computed for the ground and several excited states of both Li I and Li II by the variational method, and tables of parameters given. Additional papers, some taking into account

Refs. p. 275

polarization and exchange effects and configuration interactions, give analytic functions for Li I in the ground state[14,15,18-20,27,32] and several excited states,[18,29,32] and for Li II, also in the ground[23,26,28] and some excited[24,25] states. A ten-parameter calculation for Li II is concerned with the Lamb shift in the ground state.[26] Analytic functions taking into account the mutual distances of the electrons have been computed for the ground states of Li I[21,30,31] and Li II,[22] and a perturbation method has also been applied to Li I.[33]

Analytic functions have also been found for the negative ion Li$^-$ by the variational method.[27,34-36] Most of these indicate that the Li$^-$ ion should be stable, with an electron affinity between 0·3 and 0·74 eV.[27,35,36]

Doublet intervals for the ^2P terms have been calculated from both analytic functions[37-39] and Hartree–Fock functions;[40] a few calculations have been made for the ^3P splitting in Li II.[41]

Transition probabilities have been calculated for lines of the principal series with the use of the Hartree field,[42-47] and for lines of all series from Hartree–Fock functions.[48] The intensities of the quadrupole transitions comprising the 2*s*–*nd* 'forbidden' series have also been estimated.[49] The continuous absorption coefficient (photoionisation cross-section) has been calculated by several methods;[42,50-52] in the most recent, using Hartree–Fock wave functions, theoretical and experimental values have been found to agree reasonably well.[52]

A theoretical treatment of the isotope shift in lithium, experimental work on which is discussed above (see page 272) has been given by Hughes and Eckart,[53] and a general treatment of the effect in light elements by Bartlett and Gibbons.[54] Recent experimental work has been compared with the calculated results.[55]

X-Ray Spectrum

Early work on the *X*-ray spectrum of lithium was concerned mainly with measurement of the *K*- and *L*-absorption edges and their place in the Moseley diagram.[1-3] Energy levels were calculated on the Sommerfeld theory.[4] The results of more recent measurements have been compared with the Moseley diagram[5] and used to compile a table of energy levels.[6] Recent calculations of the absorption edges show fair agreement with experimental results;[8,9] transition probabilities have also been calculated.[7]

Other effects studied include the mass absorption below the *K*-edge,[10] the emission of secondary and tertiary rays,[11] and the Compton scattering of *X*-rays by lithium atoms.[12,13] The scattering has been compared with the results of calculations for both free and bound electrons.[14-16]

With the higher resolution now used in *X*-ray spectroscopy it has been shown that the absorption edges of atoms in the solid state have a fine structure and that, owing to the influence of conduction electrons and neighbouring atoms, many of the emission lines are in fact bands of varying width. Study of these emission and absorption bands gives valuable information about the electronic energy bands in the crystal lattice or among the conduction electrons. In the case of lithium, the fine structure of the absorption edges has been studied in the metal[20,21,27,30] and in compounds.[18,19,27] The positions and widths of many emission and absorption bands have also been measured,[17-19,21-23] and a number of calculations have been made on the subject.[7,24-26,30]

Another recent development in *X*-ray spectroscopy is the production of so-called mesonic *X*-rays (*i.e.*, *X*-rays from an atom in which the radiating electron is replaced by a meson). Information can be derived about both the atomic nucleus and the meson. In lithium, *K*- and *L*-series lines have been identified from π-mesonic atoms.[28,29]

A number of general accounts and review articles discuss the *X*-ray spectrum of lithium with particular emphasis on the importance of *X*-ray spectroscopy in solid-state physics.[31-33]

THE MOLECULAR SPECTRA OF LITHIUM AND CERTAIN OF ITS COMPOUNDS

By R. F. BARROW

The Lithium Molecule, Li_2

Lithium vapour contains a small proportion of diatomic molecules (about 1% at 1000°K.) which may be detected by means of their absorption spectrum.[1-5] The molecules are observed even on free evaporation from the heated metal into a high vacuum.[17] Three regions of banded absorption have been recognized, in the red,[10,11] blue-green[6,8,9] and near ultra-violet[12-14] regions of the spectrum: the absorption arises from three transitions A,B,C–X, respectively. The A,B–X systems have also been observed in fluorescence,[3] and the B–X system in magnetic rotation.[8] In the case of this $^1\Pi-^1\Sigma$ system, only the lines near the band-origins appear, so that the spectrum looks like an absorption spectrum with very low rotational, but not vibrational, temperature. The reduced overlapping of lines of course facilitates the analysis. The A,B–X systems have been investigated in great detail, and the isotope effect between $^7Li_2$ and $^7Li^6Li$ has been studied very thoroughly.[10,11] The band-lines of the molecule $^7Li_2$ show alternating intensity: the nuclear spin of ^7Li is found[6,7] to be 3/2. Measurements of the anomalous dispersion near absorption lines of the red system have been made;[16] they lead, however, to an incorrect value of the nuclear spin. The analysis of the red system, $A^1\Sigma_u^+–X^1\Sigma_g^+$, shows that there is a small electronic isotope shift:-

$$\begin{aligned}\nu_e^i(^6Li^7Li) - \nu_e(^7Li_2) &= -0{\cdot}064 \pm 0{\cdot}010\ \text{cm.}^{-1}\ \text{(reference 10)}\\ &\ -0{\cdot}054 \pm 0{\cdot}009\ \text{cm.}^{-1}\ \text{(reference 11)}\end{aligned}$$

(For a theoretical treatment of this effect, see reference 18).

The ultra-violet bands are less well known; no rotational analysis has yet been made, and there is some doubt whether the bands form more than one system. The most likely view is that state C is $^1\Sigma_u^+$, which gives, on dissociation, $Li(2^2S_{1/2}) + Li(3^2P)$. Other diffuse bands at shorter wave-lengths have been reported.[15]

The dissociation energy of Li_2 was measured by Lewis,[19] who used a beam in which the atoms were separated from molecules by an inhomogeneous magnetic field. The concentration of atoms was then determined by ionization on a tungsten filament and measurement of the positive-ion current. Lewis's results were supported by later work;[20] recalculated,[35] they lead to $D_0''(Li_2) = 25{\cdot}68 \pm 0{\cdot}15$ kg.-cal.mole.$^{-1}$ A very slightly higher value, 25·8 kg.-cal., is obtained[21] by extrapolation of the vibrational intervals[8] in the state $B^1\Pi_u$. It is possible that there is a real difference here, representing the height of a maximum[22] in the potential energy curve for the $B^1\Pi_u$ state.

Values of the spectroscopic constants for $^7Li_2$, taken from Herzberg[23] are given in Table III. Qualitative discussions of the lower excited electronic states have been given by Hund[24] and Mulliken.[25] The ground state is formed from ground-state atoms; the states A and B dissociate to give $Li(2^2S_{1/2}) + Li(2^2P)$. (Potential energy–distance curves are given by Mulliken[25] and Herzberg[23]). Quantitative wave-mechanical treatments of the Li_2 molecule have also been given; a Heitler–London calculation[26] gives $D_0'' = 26$ kg.-cal. and

TABLE III. - SPECTROSCOPIC CONSTANTS FOR $^7Li_2$

State	T_0	ω_e	$x_e\omega_e$	$y_e\omega_e$	B_e	α_e	r_e, A
$C^1\Sigma_u^+$	30498·8	231·5	1·5				
$B^1\Pi_u$	20395·96	269·69	2·744	−0·0637	$0{\cdot}5572_3$	$0{\cdot}0080_4$	$2{\cdot}936_4$
$A^1\Sigma_u^+$	14020·62	$255{\cdot}45_6$	1·574	+0·0018	0·49749	0·00541	3·1077
$X^1\Sigma_g^+$	0	$351{\cdot}43_5$	2·592	−0·0058	$0{\cdot}6727_2$	0·00704	2·6725

Refs. p. 279

$r_e'' = 2{\cdot}4$ A. This treatment fails,[27] however, for the state $B^1\Pi_u$. A later calculation[28] gives $D_0'' = 27$ kg.-cal.

An accurate potential function for the ground state has been given.[29] It rises more steeply at $r > r_e$ than the Morse curve: the maximum difference is about 1 kg.-cal. The applicability of the simple potential function $V = (a/r^m) - be^{-nr}$ has been considered.[30] Relations between the force constant, equilibrium distance and dissociation energy have been discussed.[31-34]

Mixed Alkali-Metal Molecules Containing Lithium

Electronic spectra of the mixed molecules LiK, LiRb and LiCs have been investigated in absorption with low resolving power.[1] Analyses have been given,[2] but the values of the constants, given in Table IV, are subject to a good deal of uncertainty. Attempts to observe an absorption spectrum of LiNa have been unsuccessful.[1,3]

TABLE IV. - SPECTROSCOPIC CONSTANTS FOR MIXED ALKALI-METAL MOLECULES

	LiNa	LiK	LiRb	LiCs
T_0(B),cm.$^{-1}$	–	17540	17500	16432
ω'(B),cm.$^{-1}$	–	126	81	77
ω''(X),cm.$^{-1}$	(252)	207	185	167

The value given for ω'' for LiNa is an estimate.[4]

Lithium Hydride, LiH

A many-line spectrum of bands degraded to longer wave-lengths, and lying in the region 3000 to 4500 A., was observed by Watson.[1] It arises from a transition $A^1\Sigma^+-X^1\Sigma^+$ in LiH, (V–N in Mulliken's nomenclature), and has been observed both in absorption, and in emission in arcs or discharge tubes. Following a preliminary analysis[2] and examination of the isotope effect[3] between ^{7}LiH and ^{6}LiH, the system was studied by Crawford and Jorgensen,[4-7] who have given a detailed account[5-7] of the isotope effect between $^7Li^1H$ and $^7Li^2H$. They also report a second system, perhaps of triplet bands, in the red region of the spectrum,[4] but this system does not appear to have been studied further. A third system, observed[22] in absorption in the ultra-violet region of the spectrum, arises from the transition $B^1\Pi-X^1\Sigma^+$. Values of the constants[6,22] for states B, A and X are given in Table V.

TABLE V. - SPECTROSCOPIC CONSTANTS FOR LiH

	State	T_0	ω_e	$x_e\omega_e$	$y_e\omega_e$
$^7Li^1H$	$B^1\Pi$	34312·26	215·5	42·4	–
	$A^1\Sigma^+$	–	234·41$_3$	–28·947	–4·185*
	$X^1\Sigma^+$	0	1405·65	23·20	0·1633
$^7Li^2H$	$B^1\Pi$	34466·27	177·28	29·13	–
	$A^1\Sigma^+$	–	180·711	–13·987	–1·1784*
	$X^1\Sigma^+$	0	1055·12	13·23	0·13
		B_e	α_e	γ_e	r_e, A
$^7Li^1H$	$B^1\Pi$	3·383	0·986	0·045	2·378
	$A^1\Sigma^+$	2·8186	–0·07831	–0·02627*	2·596
	$X^1\Sigma^+$	7·5131	0·2132	$7·5 \times 10^{-4}$	1·5954
$^7Li^2H$	$B^1\Pi$	1·908	0·427	0·006	2·376
	$A^1\Sigma^+$	1·6060	–0·01450	$-1·844 \times 10^{-3}$*	2·586
	$X^1\Sigma^+$	4·2338	0·09198	$6·7 \times 10^{-4}$	1·5949

* Higher terms known.

The significance of the signs in this Table may be illustrated as follows:-

$$\text{For } X^1\Sigma^+(^7Li^2H): \quad G_v = 1055{\cdot}12u - 13{\cdot}23u^2 + 0{\cdot}13u^3,$$
$$B_v = 4{\cdot}2338 - 0{\cdot}09198u + 6{\cdot}7 \times 10^{-4}u^3,$$

where $u = v + \frac{1}{2}$; see also Herzberg.[8]

The constants for the two isotopic species are not, as they are for heavier molecules, exactly related by the appropriate power of the ratio of the reduced masses; that this is so arises from the neglect, in the simple treatment of molecular energy levels, of certain terms,[9] including anharmonicity terms due to the interaction of rotation and vibration.[10]

The upper electronic states, $A^1\Sigma^+$, are, as is the case for the other alkali metal hydrides,[11] 'quite abnormal in that the molecules appear to *shrink* in size as well as to vibrate more rapidly as the amount of vibrational energy increases'.[7] This is attributed to the existence of a relatively low-lying state[12] which correlates with Li^+H^-. The ground state is strongly polar near

Refs. p. 281

the equilibrium configuration, but finally goes over into neutral atoms Li(^{2}S) + H(^{2}S) with increasing internuclear distance. The excited state, however, is only partially ionic in character near its minimum, becoming at larger internuclear distances largely ionic (Li^+H^-), and finally[13] going over into neutral atoms Li(^{2}P) + H(^{2}S).

The states $B^1\Pi$ are very shallow states correlating with Li(2$p\,^2$P) + H or D. Breaking off of the rotational structure of the levels in the $B^1\Pi$ state is attributed to predissociation by rotation; the observations lead to accurate values of the dissociation energy, D_0(LiH) = 56·01$_5$ ± 0·005 kg.-cal., D_0(LiD) = 56·525 ± 0·023 kg.-cal. Several theoretical treatments of the binding in the LiH molecule have been given. Heitler–London calculations give not much more than half the correct dissociation energy.[14,15] In a two-electron calculation,[16] the dipole moment was estimated to be 3·5 D., but a later, four-electron calculation[23] gives the result μ = 6·04 D. (hydrogen negative) (see also [24,25]). A treatment of the LiH^+ molecule indicates that this is unstable,[17] but in a molecular-orbital calculation, Knipp[18] obtains a dissociation energy as high as 2·$_0$ eV. for LiH, and finds that the ground state of LiH^+, $^2\Sigma$, is stable, with $r'' \sim 1{\cdot}6$ A. A more empirical discussion of the binding in the alkali hydrides has proved successful. A molecule is treated as consisting of ions, each of which is polarized by the electrostatic field of the other.[19] Good agreement is obtained between the experimental and calculated binding energies.

Variations in the spectroscopic properties of the alkali metal hydrides have been reviewed by Pearse;[11] more general variations are discussed, for example, by Sheline.[20]

Intensity measurements in the hydride spectrum may be used to determine the ^{6}Li/^{7}Li ratio.[21]

Lithium Halides: Gaseous

Accurate values of the rotational constants of the gaseous molecules have been obtained for lithium bromide and iodide from their spectra in the microwave region.[1] Observations of the Stark effect, leading to values of the dipole moments, have also been made. The magnitudes of the quadrupole coupling constants indicate that the gaseous molecules are, as expected, highly ionic.[21] Thus, for LiBr and LiI the ratios of the observed coupling constants to those expected for covalent bonds are[1] 0·048 and 0·086, respectively. Important information about the properties of gaseous lithium fluoride[13] and chloride[16] has been obtained from the molecular-beam electric resonance spectra.[23] Rotational Stark transitions $J,m_J \rightarrow J,m_{J'}$ in lithium fluoride have been studied by the same technique.[17] The absorption spectra of lithium chloride, bromide and iodide have also been studied in the vibration-rotation region.[2] Only broad, unresolved bands are observed, but they suffice for the determination of the fundamental vibration frequencies. No indication of the presence of dimers was found in these investigations, although several different lines of evidence, e.g. from mass-spectrometric[3] studies, molecular beams[4] and vapour pressure,[5] show that the alkali halide vapours, like those of the hydroxides, do not always consist solely of monomeric species.

The visible or ultra-violet spectra of the gaseous alkali halides arise by transitions from the ground state, $X^1\Sigma^+$ in all cases, to one or more excited states correlating with the neutral atoms. Little is yet known in detail about these excited states. They are repulsive, or at the least possess small minima, so that the spectra are either continuous, or show fluctuation bands.[6-8,15,18] It seems likely[9] that the strongest continuum at shortest wavelength is a transition $0^+ \leftarrow X^1\Sigma^+$, while the fluctuation bands at longer wavelengths arise from the transition $1 \leftarrow X^1\Sigma^+$. The spacing of the fluctuation bands reflects the spacing of the vibrational levels in the ground state and the slope of the potential energy–distance function for the excited state. Thus, by making certain assumptions, it is possible from measurements of the fluctuation bands to derive estimates not only of the vibration frequencies in the ground states but also of the dissociation energies.[6,7] However, the dissociation energies of these molecules are now best determined thermochemically according to the equation:-

$$D(\mathrm{MX}) = -Q_f(\mathrm{MX}) - \Delta_s H(\mathrm{MX}) + \Delta_s H(\mathrm{M}) + \tfrac{1}{2}Q_f(\mathrm{X})$$

where $D(\mathrm{MX})$ is the heat of dissociation of the halide MX into ground-state atoms, M and X;

Q_f is the standard heat of formation, and

$\Delta_s H$ the heat of sublimation.

Likewise the most reliable values of the vibration frequencies are probably those determined from the infra-red spectra.

The ultra-violet absorption spectrum of gaseous lithium fluoride has not yet been observed; work on the other lithium halides has been reported as follows; lithium chloride,[8,14] lithium bromide,[8] lithium iodide.[6,8,15]

A discussion has been given of the effect on the dipole moment of isotopic substitution,[19] and the measurement of mass ratios[20] from microwave spectroscopic information has been considered.

Values of the spectroscopic constants of the gaseous lithium halides are given in Table VI.

Refs. p. 283

TABLE VI.- SPECTROSCOPIC CONSTANTS FOR THE GASEOUS LITHIUM HALIDES

Molecule	B_e[b]	α_e[b]	r_e, A	$\omega_e$cm.$^{-1}$	μ, D.
LiF	-	-	[1·527][e]	720[f]	6·6[13]
LiCl	-	-	[2·022]	662[2]	-
LiBr	19162·32[c]	208·8[c]	$2{\cdot}170_4$	576[2]	6·19 ± 0·15
LiI	15381·99[d]	152·6[d]	$2{\cdot}391_9$	501[2]	6·25 ± 0·20

Notes.
- a. The values are taken from reference 1, except where otherwise indicated. Values in square brackets are estimated values.
- b. The values of B_e and α_e are in Mc./sec.
- c. Constants for ^{6}Li^{79}Br.
- d. Constants for ^{6}LiI.
- e. According to [13], r_0(^{7}LiF) = 1·51 ± 0·08 A.
- f. This figure for ^{6}LiF is the mean of two discordant observations,[13] ω_e(^{6}LiF) = 756 ± 38 cm.$^{-1}$, ω_e(^{7}LiF) = 646 ± 32 cm.$^{-1}$

Dissociation Energies, D_{298}, kg.-cal.mole^{-1}

	LiF	LiCl	LiBr	LiI
$-Q_f$(MX)	146·3[10]	97·70[10]	83·72[10]	64·79[10]
$-\Delta_s H$(MX)	-66·3[5]	$-48{\cdot}_0$*	$-46{\cdot}_1$*	-44·5[3]
$\Delta_s H$(M)	38·44[11]	38·44	38·44	38·44
½Q_f(X)	18·86[a]	29·01[10]	26·71[10]	25·48[10]
D_{298}	137·3	$117{\cdot}_2$	$102{\cdot}_8$	84·2

* Estimated, from figures given by Kelley.[12]

a. Recalculated, from [22]

COMPOUNDS OF LITHIUM: SOLID STATE

Lithium Hydride

The ultra-violet absorption spectra of thin layers of the hydride and deuteride have been observed.[1-3] Maxima were first found at 2517 and 2482 A., respectively,[2] but in later work[3] no maximum was found at $\lambda > 1860$ A. The elementary photochemical process is considered to be an electron jump from the anion to the cation within the lattice (see page 285 and ref. 5 on page 286).

Lithium Hydroxide

The infra-red absorption spectra of thin sheets of solid LiOH and $LiOH,H_2O$ have been examined for the normal, partly deuterated and fully deuterated compounds. It is concluded[1] that both hydrogen atoms from each water molecule are used in forming strong hydrogen bonds in the hydrate. The fundamental vibration frequency of OH^- in LiOH was found to be 3839 cm.$^{-1}$

Lithium Halides

In order to avoid repetition, certain properties of the crystalline alkali metal halides are discussed in detail under only one appropriate alkali metal, as follows: ultraviolet absorption spectra, page 285; Raman spectra, Sect. XXXIX; colour centres, luminescence and phosphors, under the spectra of potassium halides.

The alkali-metal halide crystals, like other ionic crystals, absorb radiation both in the infra-red and in the ultra-violet regions at characteristic frequencies.

In the infra-red, the characteristic frequency corresponds to the maximum frequency of lattice vibration in which the positive and negative ions move in opposite directions. These frequencies may be calculated from other properties of the crystal.[1,2] The observed widths of the absorption bands are, however, far greater than those calculated according to a simple model, and the transmission curves often show a structure, suggestive of the presence of more than a single absorption line.[3,22-24]

Refs. p. 286

The longest-wave-length absorption band in the ultra-violet region of the spectrum is considered to arise from the transition:-

$$M^+ + X^- + h\nu \rightarrow M + X$$

in which an electron is transferred from a halogen ion to a neighbouring cation. The energy required for this process may be evaluated as follows:-[4]

	Work done
(1) A negative ion is removed from a normal site in the lattice to infinity	$\alpha\mathbf{e}^2/r$
(2) An electron is removed from this ion	E
(3) The neutral halogen atom is replaced in the vacant lattice site	0
(4) An adjacent positive ion is removed to infinity	$(\alpha-1)\mathbf{e}^2/r$
(5) An electron is added to the positive ion	$-I$
(6) The neutral alkali atom is replaced in the vacant lattice site	0

Here α is the Madelung constant, $\mathbf{e}$ the electronic charge, r the smallest anion–cation distance in the lattice, E the electron affinity of the halogen atom and I the ionization potential of the alkali atom. The total work done is:-

$$\begin{aligned} W &= (2\alpha-1)\mathbf{e}^2/r + E - I, \\ &\equiv Q + E - I, \end{aligned}$$

where Q is the coulomb part of the lattice energy. The values of W calculated in this way are higher[21] than the observed values of $h\nu$, but inclusion of the changes in the polarization energy caused by the electron transfer improves the agreement.[5] Further improvement results when account is taken of the interactions of the atoms, particularly of the alkali atom, with the neighbouring ions, and there is little doubt that this process describes correctly the transition in the longest-wave-length ultra-violet absorption band (for a discussion of the shorter wave-length bands, see, for example [3,25]).

The infra-red absorption maximum for lithium fluoride[6] lies at 32·6 μ.

In the ultra-violet region, maxima have been located[7-9] as follows:-

LiF	<1100 A.	LiCl	1430 A.	LiBr	1730 A.	LiI	2120 A.
			1300		(1620)		1970
					1560		(1830)
							1760
							(1670)
							(1400)
							(1200)

The reflexion of electrons at crystalline films of the alkali halides is minimal for electron energies corresponding to the known limits of optical transparency.[27] The reflectance of lithium fluoride in the region 1200 to 2000 A. has been measured.[28]

Lithium fluoride is an important optical material: in the infra-red its transparency[10-12] limits its use to $\lambda \leqslant$ 5·3 μ, but in the Schumann region it absorbs little[13-15] until about 1300 A., and good samples may transmit useful amounts of radiation at wave-lengths of about 1100 A. On account of this property, it finds a use as a material for windows, lenses and prisms for the spectroscopy of the vacuum ultra-violet region.[15] It may also be employed in achromatic lens combinations to cover a wide spectral region.[16] An *X*-ray spectrograph using a lithium fluoride crystal has been described.[17]

A theoretical treatment of the Raman spectrum of crystalline lithium fluoride has been given,[18] but this has by no means found universal acceptance[19] (see also Sect. XXXIX).

The Raman spectrum of aqueous lithium chloride indicates a high degree of dissociation; no spectrum other than that of water is observed even in 13N. solutions.[20] Enolization in solutions of lithium bromide in acetone has been studied[26] by observations of their infra-red absorption spectra.

Colour Centres

In the section on the spectra of potassium halides some mention is made of colour centres in the crystals of the alkali halides. Investigations of colour centres and luminescence have also been reported for the lithium halides, particularly lithium fluoride. This substance, however, shows unique characteristics,[1] some of which may arise from traces of impurities. Reference may be made to the following reviews[1-4] and papers.[5-11]

SECTION XX

THE ANALYTICAL DETERMINATION OF LITHIUM

By H. V. THOMPSON

DETECTION

In the detection of lithium by wet tests the usual procedure is first to prepare a solution containing only the chlorides of the alkali metals and, if necessary, further concentrate the lithium by taking advantage of the much greater solubility of anhydrous lithium chloride in various organic solvents (see below). Alternatively, picrolonic acid has been recommended,[1] as it precipitates sodium, potassium, ammonium and the alkaline earths, but not lithium. Formerly, lithium was generally detected by precipitation of its relatively insoluble phosphate, fluoride or carbonate,[2] but other reactions are now available including the use of an ethereal solution of ammonium stearate,[3,4] hexamethylenetetramine in the presence of potassium ferricyanide,[4-7] alizarin Red S,[4,8] alkali metal arsenite in methyl or ethyl alcohol[9] and precipitation as the acid aluminate,[10] or in alkaline solution as lithium potassium ferric periodate.[11,12] With a number of azo dyes, lithium salts give colour reactions in alkaline solution which are said to be highly sensitive;[13,14] fluorescence tests for the detection of lithium have also been described.[15,16] After separation of the alkali metals by paper chromatography lithium is detected on subsequent development of the chromatogram.[16a] A physical test, claimed to be sensitive to 10^{-6}g. of lithium, depends on the action of molten lithium salts on soda–lime glass, whereby the sodium ions in the glass are replaced by lithium ions from the molten salt and the glass becomes superficially fractured and opaque.[17]

When present in mere traces lithium is best detected spectrographically. As a general rule reliance is placed on simple spectroscopy, *i.e.* the old-established flame test, to indicate the presence of lithium before any confirmatory tests are undertaken, and in applying this test the sensitivity can be much enhanced by the use of a filter,[18] 2 cm. in thickness, consisting of an aqueous solution of coccinin (0·14%), Dahlia Violet (0·0014%) and $CuSO_4,5H_2O$ (0·7%).

DETERMINATION BY CHEMICAL METHODS

Gravimetric methods.

In the standard gravimetric processes for the determination of lithium, the mixed alkali chlorides are obtained in a solution from which all other metals and acid radicals, as well as ammonium salts and organic matter, have been eliminated. After evaporation and drying, the mixture of anhydrous chlorides is extracted with an organic solvent or solvents in which only lithium chloride is significantly soluble. Among such solvents are amyl alcohol,[19-27] ethyl alcohol–ether,[24,28-32] *iso*butyl alcohol,[33-35] 2-ethylhexanol,[36] acetone[37-39] and dioxan.[40] Other solvents have also been recommended.[41,42]

Although such a variety of solvents is available, in practice the choice narrows considerably, and it seems probable that in most determinations either Gooch's amyl alcohol process[19] is used, or extraction with a mixture of alcohol and ether by Palkin's modification[29] of Rammelsberg's original method[28] is employed.

The lithium chloride thus separated is often converted into sulphate and weighed as such;[27,42,104,105] alternatively the lithium may be determined as lithium zinc (or nickel) uranyl acetate.[27,43-47,104] Another procedure is to treat a mixture of sodium and lithium perchlorate, dissolved in anhydrous *n*-butyl alcohol, with a solution of hydrogen chloride in *n*-butyl alcohol, when the sodium perchlorate is converted into chloride and the lithium salt, which alone remains in solution, is determined as sulphate.[48,49]

A method recently described for the determination of microgram quantities of lithium in the presence of excess of sodium and potassium salts involves precipitation as the complex $2Li_3Fe(CN)_6,K_3Fe(CN)_6,5(CH_2)_6N_4,6H_2O$ from an acetone–water mixture.[50] Other methods proposed for the determination of lithium are as the fluoride,[23,51-54] the phosphate[27,55] and the aluminate,[27,42,56,57,104] $2Li_2O,5Al_2O_3$. Ion exchange chromatography has been applied to separate lithium from sodium and potassium and the lithium can then be determined by any appropriate method.[57a]

Volumetric Methods.

The volumetric determination of lithium is limited in scope and none of the few suggested processes has gained any substantial measure of general acceptance. Solvent extraction of lithium from a mixture of the anhydrous alkali metal chlorides enables the lithium to be determined by a Volhard titration.[36] In the periodate process lithium is precipitated either as such or as lithium potassium ferric periodate, $LiKFeIO_6$, and, after adding an excess of potassium iodide to an acid solution of the washed precipitate, the liberated iodine is titrated.[58-60] Other suggested procedures are to convert the lithium salt into borate with subsequent titration of the boric acid,[40] and a difference method based on the conversion of the mixed alkali chlorides into carbonates and titration of aliquot portions of the solution before and after removing the lithium carbonate.[61] If isolated as lithium zinc uranyl acetate, lithium can be determined volumetrically by the method used for sodium (see Sect. XL).

DETERMINATION BY PHYSICAL METHODS

Polarography.

A direct determination of lithium is possible by polarographic methods,[62-64] because its half-wave potential is sufficiently far removed from those of the other alkali metals to give a simple and not a cumulative wave in mixed solutions.[65-67] The usual practice is to carry out the determination with aqueous tetraethylammonium hydroxide as the supporting electrolyte in an aqueous solution of alcohol containing only the alkali chlorides, provided that not more than a ten-fold excess of sodium or potassium is present;[67] otherwise a preliminary concentration of the lithium is necessary.

Flame Photometry.

When lithium is present neither as a trace element nor as a dominant constituent, the modern technique of flame photometry certainly provides the quickest method for the determination of lithium:[68-77] it is probably as precise as any and has been found particularly useful in the analysis of silicates. Such materials are first evaporated almost to dryness with hydrofluoric and sulphuric acids and from the fluoride-free residue an acid solution containing only metal sulphates is obtained. When this solution is atomized in the coal-gas burner of a simple flame photometer provided with a suitable interference filter, lithium can be accurately determined in the presence of at least a ten-fold excess of sodium, potassium or calcium, and predominant quantities of aluminium do not interfere. However, with other types of material, according to their composition, it may be necessary to remove certain of the cations before the solution is atomized.

Spectrography.

A considerable volume of work has been published on the spectrographic determination of lithium and, although this method is not necessarily restricted to determining traces of lithium, it is particularly valuable when the concentration of the element is below the effective limit of chemical methods.

An approximate determination accurate to about 0·001 mg. of lithium can be made by the progressive dilution of a prepared solution until the line 6708 A. is either just visible or just fails to appear when the flame is viewed through a simple spectroscope.[78,79] For more precise work or smaller quantities of lithium, arc,[80-86] spark[87-90] or flame[91-98] spectrum methods must be used, the actual determination being usually made by an internal standard technique or by a simple comparison standard procedure.

Colorimetry.

When lithium has been separated as its complex ferric periodate (see page 289), the iron in the precipitate can be determined colorimetrically.[99] The colorimetric process used for determining sodium after precipitation as its triple acetate (see Sect. XL) is applicable in the same circumstances to lithium.

Reagents for the detection and determination of lithium are dealt with in a number of reviews on the analytical chemistry of the alkali metals.[100-103]

SECTION XXI

BIOLOGICAL PROPERTIES OF LITHIUM

By F. CALL

Effect on vegetation

Since lithium is widely though sparsely distributed in soils, it is not surprising that it is found to be present in most plants. Quantitative spectrographic determinations have been carried out on a large number of species and collected data are available.[1-8] The content varies from 0·09 to 9·5 parts per million on a dry weight basis, averaging 1·29p.p.m. for cryptogams and 2·06 for phanerogams. The *Gramineae* (grasses and cereals) and *Liliaceae* are poorest, the lowest content, 0·09p.p.m., found being in the pollen of the lily. The stalk, ovaries and anthers had less than 1p.p.m. but the leaves and petals contained up to 2·5p.p.m. The roots usually have a higher lithium content than the aerial parts of the plant, while the phloem exudate of species of *Fraxinus*, *Platanus*, *Robinia* and *Cucurbita* was often richer in lithium than the parenchyma sap.[9] The element was also present in the skin of the mushroom.[10]

Plants grown in soils rich in assimilable lithium varied widely in the amounts taken up; thus alfalfa takes up very little and tomato a great deal.[11] This suggests that plants may differ greatly in their ability to absorb lithium. The rate of absorption by rice of lithium from aqueous solutions actually decreased as the concentration of the solution increased[12] while the rate of absorption by *Chara ceratophylla* increased, but not proportionately, being stimulated by light and not attaining equilibrium in fourteen days.[13] There was no loss of lithium from the latter species on transfer to lithium-free solutions but with wheat, although lithium in the older leaves appeared to be immobile it was readily lost from the roots.[14] In contradistinction to the distribution found in plants grown in soil,[2] sixteen species grown in nutrient solutions had a higher content of lithium in the shoots than in the roots.[15] No significant differences were found in the distribution or content of lithium in lentils grown in different soils.[16] The cotyledonous leaves of the broad bean are able to absorb lithium but not barium or thallium from aqueous solution[17] and a similar selective absorption is shown by some fruits.[18] Lithium was found to be transported vertically in the woody stems of the willow, being, unlike water, unable to pass laterally across the stem.[19] Kinetic studies of the absorption of alkali cations by barley roots indicated that lithium was not competitive with potassium or rubidium but in fact increased the rate of absorption of rubidium.[20] The amounts of lithium taken up by other plants could not be correlated with the uptake of other cations, the ratio varying with age of plant, species and a number of other factors.[21-24] Substitution of equivalent amounts of lithium for potassium resulted in decreased yields of wheat and the plants died as soon as potassium had been completely substituted.[25] The lithium content of walnut trees was found to be independent of the presence or absence of manganese deficiency.[26]

At low concentrations lithium has a definite stimulating effect on the germination of many seeds[27-29] and on the subsequent growth of the seedlings.[30–33] Although a very productive soil has been found to be characterised by the presence of lithium among other elements,[34] reduction of the pH of such a soil may result in the absorption by plants of toxic amounts of lithium.[35] At higher concentrations lithium is the most toxic of the alkali metals[36,37] and has been shown to be responsible for a specific mottle leaf disease in citrus.[38–40] The application of carefully regulated doses of lithium salts gives effective control of many bacterial and fungal diseases of plants, notably of powdery mildew, *Erisyphe sp.*[41–48] There have been a number of attempts to discover a fundamental effect on the plant cells of lithium among other alkali metals by cytological methods,[49–53] permeability measurements[54–56] and determinations of membrane potentials[57] but the results are largely inconclusive.

Effect on Micro-Organisms

Bacteria, and especially actinomycetes and fungi, in soil are stimulated by the addition of lithium salts.[58] Lithium chloride can be substituted for sodium chloride in the culture of *Vibrio costicolus*[59] and it has been suggested that lithium may be an essential factor for growth in the symbiosis of *Rhodotornia rubra* and *Mucor ramanianus.*[60] In higher concentrations lithium salts are, however, definitely toxic to fungi.[61] The toxicity of lithium halides to *Penicillium italicum* was found to increase with the atomic weight of the halogen and there was some indication that the lithium ion was relatively non-toxic,[62] but the metallic ion appeared to be the toxic agent in the case of the slime moulds, myxomycetes.[63] Lithium has been included in a number of investigations of the toxic effects of metals on bacteria.[64–72] In a paper covering thirty nine different species of bacteria and fungi, lithium was reported to be the most toxic alkali metal after cæsium for both bacteria and fungi.[64] The action was bacteriostatic rather than bactericidal and lithium was in fact slightly superior to cæsium as a bactericide at high concentration. The toxicity of lithium ions to three organisms was markedly decreased by reducing the pH of the medium from 6·5 to 5·0.[72,73] An interesting property shown by lithium salts is that of inducing morphological changes in bacteria,[73–79] manifested by different habits of growth. Thus *Chromobacterium violaceum* forms atypical secondary colonies of large papillae,[73] *Escherichia coli* changes to vacuolated amoeboid forms[75] while *Aerobacter aerogenes* changes from a ropy to a non-ropy form.[78]

These changes may be associated with changes in the permeability of the bacterial cell wall.[74] One interesting suggestion is that the changes are due to accumulation of metabolic products which lower the pH of the medium, thus causing the lithium ion to become more toxic to the parent than to the secondary form.[73]

Similar morphological changes have been observed in algae,[80] while strains of brewer's yeast, *Saccharomyces cerevisiae*, have been found to grow successfully in normal lithium chloride solution, the resistant mutant being dominant.[81] Lithium salts cause reversal of the beat of the cilia of the protozoon *Paramecium*, the adaption taking about 18 hr.; but no tolerance to toxic concentrations of lithium halides could be induced in this species by exposing the organism to sub-lethal concentrations.[83] Lithium salts gave some protection to *Paramecium* against injury by freezing[84] and were less toxic to *Spirogyra* than sodium or potassium salts.[85] The rate of absorption of bacteriophage by *Escherichia coli* was increased by low concentrations of lithium salts but depressed by higher concentrations.[86]

Lithium in Marine Organisms

Although lithium is present in sea water there has been little study of the uptake by marine organisms, but the element has been shown to be present in the common brown algae, *Laminariaceae* and *Fucaceae*[87] and in the embryo of the cephalopod, *Sepia officinialis.*[88]

Effect on Animals

(*a*) Distribution

The widespread occurrence of lithium in plants suggests that it would also occur in animals and a study of the ash of thirty seven samples of invertebrates, fish, batrachians, reptiles, birds and mammals, shows that lithium is present in all except turkey egg yolk.[89] Invertebrates generally contain more, 0·05 to 5·8mg./kg. dry ash, than vertebrates, 0·024 to 0·77mg./kg. The element has also been identified in the ash of dog liver,[90] most organs and tissues of the white rat,[91] silkworm larvae,[92] and guinea-pigs.[93] Lithium is said to occur spasmodically in human tissues[94] but it has been found present in 95·7% of specimens examined of reproductive organs, stomach, thyroid and placenta, and in hydatid cysts,[95,96] to the extent of 0·01 to 0·1% of the ash. It also occurs in the brain,[97] in tumour tissue[98] and in blood where it is largely confined to the plasma, the content ranging from 9 to 30mg./l., with an average of 19mg./l.[99] Although lithium was found to be present as the phosphate in human teeth and bone,[100] a later investigation found no trace in bone specimens from thirty three individuals.[101]

The element is usually present in human milk and cows milk,[102-105] although sometimes absent,[103] and in eggs.[106] Although ingested lithium salts are absorbed and rapidly excreted in the urine, lithium in natural foods is poorly absorbed.[107]

(*b*) Effect on Enzyme Systems.

The effect of lithium on enzyme systems has been summarized.[108] In general the lithium ion behaves as an activator but its role is not clear cut and the anion may play an important part. Thus although lithium sulphate has a specific inhibiting effect on acid liver phosphatase,[109] other salts of lithium may enhance the action of this enzyme system.[110] Lithium salts of ester phosphates are split by slightly acid phosphatase[111] as is lithium acetyl phosphate by the appropriate enzyme.[112] The metabolism of octanoic acid by liver slices is greatly stimulated by lithium ion[113,114] but there is only a slight effect on the respiration of mitochondria in the presence of Krebs cycle intermediates.[115] Weak activation also occurs with deoxyribonuclease,[116] human serum hydraluronidase[117] and alfalfa pectinesterase.[118] Lithium has a negligible effect on the formation of amylase by *Aspergillus oryzae*[119] and cannot replace sodium in stabilizing the activity of plant carbonic anhydrase.[120] Definite though weak inhibition occurs with the lipase of the castor oil plant,[122] urease,[123] plant peroxidases,[124] pepsin,[125] tryptophanase,[126] succinate decarboxylase[127] and the acetate-activating enzyme system.[128] Lithium has no effect on tyrosinase action.[129]

(*c*) Effect on Animal Tissues.

The conversion of fibrinogen to fibrin is inhibited by lithium salts though not so effectively as by calcium salts.[130 132] Solutions of lithium chloride or bromide in the absence of calcium are, however, able to dissolve fibrin clots to form fragments resembling fibrinogen in size and shape, an apparent reversal of the clotting reaction.[133] No specific interaction could be demonstrated between lithium hydroxide and hæmoglobin from man, horse and dog.[134] Lithium ions, in common with the alkaline earth metal ions, exert a marked protective action on the deterioration of guinea pig complement at concentrations of 1×10^{-5}M. but accelerate the deterioration at higher concentrations.[135] Antibodies to lithium chloride, which do not however flocculate, have been demonstrated in rabbits.[136] It is found that lithium ions compete with sodium ions but not with potassium ions for transport into the human

Refs. p. 298

erythrocyte,[137,138] the ratio between sodium and lithium penetrating being 1·0 to 0·93. A similar competition with sodium has been found to occur in isolated frog skin which has the ability to move lithium against an electrochemical gradient.[139,140]

The initial effect of lithium on neural tissues is largely that of excitation. Thus the respiratory quotient of guinea pig brain is increased, probably owing to an increase in cell permeability,[141] while motor activity is excited in the sensometor cortical centres of the dog.[142] The isolated frog nerve is depolarized by 0·11N. lithium salts, the depolarization being reversible by sodium ions at first but becoming irreversible after 500 minutes.[143,144] The depolarization is delayed at low temperatures, and unlike the effect produced by sodium ions, is preceded by a phase of hyper-polarisation.[145] Lithium resembles sodium in being able to prevent the blocking effect of potassium on nerve conduction.[146] A similar resemblance to sodium is found in the effect on the bioelectric potentials across the protoplasm of *Valonia macrophysa*, the apparent mobilities of the ions in the surface layers being of the same order.[147]

In general lithium lowers the excitability of muscle although the action is complex. The intestine of the chick embryo is stimulated at all stages of development, the action being directly on the muscle and not on the parasympathetic nerves.[148] On the small intestine of the cat and guinea pig increasing concentrations of lithium ions produce first a transitory paralysis, then a brief contraction, and finally a diminution of the peristaltic movements.[149,150] Although this action is similar to that of sodium ions, lithium cannot be substituted for sodium since the excitability is gradually lost in lithium solutions.[151] The order of effectiveness of ions of the alkali metals is not always the same, since lithium is more effective than sodium in causing elongation of the frog stomach muscle[152] but less effective in its action on *Mytilus* muscle.[153] Lithium opposes the contraction of striated muscle caused by veratrine, though less effectively than potassium,[154] while blood vessels become relaxed and hence dilated.[155-158] The irritability of isolated heart muscle is increased by low concentrations of lithium ions[159] while the whole heart is slowed and soon stopped.[160-163] The action of lithium here seems to be antagonistic to that of potassium.[164] The injury potential of smooth muscle is lowered by isotonic concentrations of lithium chloride.[165] The effect on the membrane potential and threshold current for excitation have also been studied.[166,167] The electrocardiograms of animals with a high serum lithium content show marked similarities to those obtained when the serum potassium is high, suggesting that lithium may displace potassium from the cells.[168] Lithium ions have been found to induce rhythmical potential and impedance changes in isolated frog skin[169] when sodium, but not potassium, ions are in contact with the opposite side of the skin. The waves have an amplitude of about 5mV. and a period of three minutes. There have been a few attempts to demonstrate changes in the muscle protein caused by lithium ions.[170-172] The *X*-ray pattern of moist whole frog muscle consists of two rings corresponding to spacings at 4·46 and 9·66A. with signs of orientation in both rings. After treatment with hypertonic concentrations of lithium chloride, the orientation disappears, an additional ring appears at 21·3A. and the outer ring at 9·66A. is split.[170] It is interesting to note that lithium chloride removes the anomalous electrophoretic pattern normally exhibited by the protein, wheat gliadin, a change ascribed to a difference in hydration.[173] The same salt also gave some protection to isolated chromosomes exposed to agents known to produce protein denaturation.[174] No significant changes were evident in the chromosomes of intact cells when treated with lithium salts.[175]

Lithium salts have no appreciable effect on the sense organs of the frog palate,[176] of the eel[177] nor of the aquatic beetle *Laccophilus maculosus*,[178] but are very effective repellants of the termite, *Cryptotermes brevis*.[179]

(*d*) Morphogenetic Effects

A great deal of attention has been devoted to one of the most interesting biological properties of lithium salts which is apparently unique, that of causing abnormalities in developing embryos. Test animals in which the effect has been observed include some twelve species of sea urchin, ascidians amphibians, fish, planarians, pond snails and the fruit fly *Drosophila*. The abnormalities include the development of monsters, which are tailless or headless, with only one eye or none and with concomitant changes in the underlying tissues and structures.[180-185] The abnormalities in *Drosophila* involve the male terminalia and the venation of the wings.[186] Lithium chloride also inhibits the growth of cultures of chicken embryonic heart fibroblasts[187] and of tumour tissue growing in association with chicken embryos and eggs,[188] although the growth of the embryo itself may not be affected. Morphological changes are obtained by treating all stages from the earliest stage of the egg, and susceptibility tends to decline with the stage of development, although there may be a rise in susceptibility at the twenty four cell stage.[189-197] Abnormalities may also be produced by direct injection of lithium chloride solution into the embryo.[198] The effect of temperature appears to depend on the stage at which treatment commences, the number of abnormalities increasing with temperature at an early stage of development but decreasing at later stages.[199] Lithium hinders head regeneration of the worm, *Planaria*, at 3°C. but not at room temperature.[200] Abnormalities appear after treatment with concentrations of the order of 0·0025–0·025M. for one hour[201-206] and have been observed after treatment with 2·4 × 10^{-5}M. for twenty four hours.[207] The first manifestation is an abnormality in the formation of the primitive body cavity (exogastrulation).[208-210] Since the animal pole is suppressed at the expense of the vegetal pole of the embryo, the process is often termed vegetalization.[211,212] Lithium affects only the dorsal-ventral plane of the organism and not its bilateral symmetry.[213] Exogastrulae arise by inhibition of the outermost layer of cells, the ectoderm, rather than of the inner layer or entoderm. The specificity of lithium is thus regarded as residing in its power of localised action on certain specialised regions of the embryo,[209,210] thus causing differential rates of growth, though later stages such as head malformation may be due to interference with the chemical organisers.[214] The action of lithium is intensified by centrifuging the eggs before treatment.[215,216] Lithium salts have a protective action on the ability of the egg to form the fertilization membrane[217] and the element is normally present in this membrane in trace amounts.[218] Lithium also inhibits the animalising action of trypsin on eggs.[219] Lactic acid weakens the morphogenetic effects of lithium in some species but reinforces them in other species.[220] An antagonistic action is shown by calcium ions,[207,221-223] potassium ions,[22,223] cyanide ions,[221,224] sodium azide[225] and pyocyanine.[226,227] There have been attempts to interpret the morphological effects of lithium in terms of the state of hydration of the intracellular proteins[228-233] and salt solutions do in fact produce an increase in the viscosity of the proteins, but the effect is not specific to lithium. Apparently the presence of oxygen is necessary for the production of abnormalities since lithium has no effect on embryos under anaerobic conditions.[234] Both glycolysis and respiration of eggs are reduced by about 20% by lithium ions[235-237] while glycogenesis is increased.[238,239] Certain of the abnormalities have in fact been attributed to a change in the carbohydrate metabolism.[240,241] Treatment with lithium salts causes a change in the content of certain amino acids[242] and an increase in deoxyribose nucleic acid,[243,244] but no change in in the level of homarine.[245] There are marked changes in the activities of certain enzymes[246,247] and it has been suggested that treatment with lithium salts inhibits the development of mitochondria which contain a series of enzymes active in the synthesis of proteins required for development.

Refs. p. 298

(*e*) Toxicity

Lithium was less toxic than potassium to tadpoles[248] and depressed the oxygen consumption of surviving frog skin less than potassium and the alkaline earths.[249] When injected suboccipitally into rabbits lithium chloride was among the least toxic of a series of salts of heavy metals[250] but was markedly toxic by intravenous injection, a rise in blood pressure being produced by as little as 3·3mg.[251] Lithium salts have a paralysing effect on the spinal cord and nervous system.[252,253] There is some evidence of bone lesions caused by stimulation of the osteoblasts.[254] Lithium lactate administered in the food of rats was highly toxic and caused a fall in weight.[255] The toxicity has also been studied on a variety of plant cells, fish, bacteria and isolated mammalian organs.[256] Calculations show that the presence of lithium in tissues is unlikely to increase significantly the radiation dosage arising from the $(n,p)(n,\alpha)$ reaction following exposure to thermal neutrons.[257] Lithium chloride is toxic to human spermatozoa[258,259] and increases the fragility of human red blood cells.[260] There have been a number of cases of lithium poisoning among patients using the salt substitute 'Westsal' (a solution of lithium chloride with citric acid and potassium iodide). Several fatalities have occurred among patients with arteriosclerosis and lithium was regarded as contributing to the cause of death. Patients on a low sodium diet appeared to have increased susceptibility. The symptoms were extreme muscular excitability and irritability, uncontrollable tremors, mental confusion and apathy, blurring of the vision and finally coma. A dose of 4–5g. has given severe symptoms.[261-264] When administered orally to dogs and rats lithium is readily absorbed and distributed uniformly throughout the body water, being excreted almost entirely in the urine. The salt is more toxic and accumulates at a faster rate when the sodium intake is restricted.[265-267] Although lithium salts were formerly used to dissolve uric acid present in the body in certain diseases, it has been shown that it is not possible to attribute any particular solvent properties to these salts,[268] although lithium taurocholate in combination with taurine is stated to be effective for the prevention and dissolution of gall stones.[269] Lithium antimony thiomalate has been proposed as a trypanocide,[270,271] while injections of lithium salts have been employed to treat streptococcal infections.[272] The duration of evipan anæsthesia is increased by administration of lithium salts but there is very little effect on the local action of cocaine and procaine.[273,274]

CHAPTER II

SODIUM

SECTION XXII

THE OCCURRENCE OF SODIUM

By K. W. ALLEN

No important new sources for the extraction of sodium or its compounds have been discovered since the publication of the original Treatise. Advances have been made largely in the investigation of various minor occurrences and also to a lesser extent in fuller understanding of previously known examples.

Various reviews have appeared giving general information and statistics of the production of sodium salts including borax, salt, and the nitrate, sulphate and carbonate.[1-4]

Perhaps the largest and most important new field has been in the investigations of the occurrence of sodium outside the earth's surface, viz. in the atmosphere, the stratosphere and inter-stellar space and in meteorites, the sun, stars and novæ. Air of the Venetian beach has been found to contain 0·000183 g. of sodium chloride per cubic metre, and the rain falling there from 0·0031 g. to 0·0286 g. per litre of total chloride expressed as sodium chloride.[5]

Studies of sodium occurrence in the stratosphere have depended upon examination of spectra, mainly of twilight and the night sky. Bernard concluded that a layer of excited sodium atoms of terrestrial origin existed at a height of about 60 kilometres.[6-9] Cabannes, Dufay and Gauzit suggested that the layer was at a height of 130 kilometres and arose from meteoric dust of cosmic arigin.[10,11] Later, it was thought that the sodium atoms were emitted from the sun.[12] Vegard and others studied the spectra of auroræ and confirmed the sun as the source of the sodium and further calculated that the layer which contains the sodium atoms extends from a height of 43·7 kilometres to 105·4 kilometres.[13-15] Two recent reviews confirm this generally but indicate heights between 42·5 and 104·5 kilometres.[16,17]

Merrill has made an extended study of the spectra arising from interstellar gas and concludes that this consists of clouds of highly attenuated sodium vapour (and the vapours of some other metals) stretched at irregular intervals between the stars.[18-20] Adams has published a general review of of this problem.[21] Brown and Patterson have examined the analyses of a number of meteorites, and for the silicate phase report an average value of 4·62 ± 0·36 atoms of sodium per 100 atoms of silicon.[22]

The atmosphere of the sun has attracted some careful study and several estimates have been made of the relative abundance of various elements including sodium, which occurs to the extent of approximately one atom per million atoms of all kinds or 0·002% by weight.[23-26]

Neutral atoms of sodium have been detected in some stars,[27,28] while sodium ions have been detected in several others.[29-32] The spectrum of ρ-Cassiopeiæ has shown considerable variation in the amount of emission and absorption due to sodium over the years 1939 to 1947 and it is hoped that this may lead to a better understanding of the formation and dissociation of molecules in the stellar atmospheres.[32]

During their periods of maximum brightness the spectra of many novæ (stars which suddenly increase in brightness and then fade to their original luminosity) have been recorded and studied and in almost all cases the presence of sodium has been reported.[33-38] Nova T Coronæ Borealis, 1946, has been the subject of particular study and all observers comment on the strength of the sodium emission in the early stages of the outburst.[39-41]

Little new information has been published on the mineralogical occurrence of sodium within the earth's crust, and most of such reports have been incidental to some other investigation.

Kundig and de Quervain have reviewed the mineral resources of Switzerland, including the sodium ores.[42] Granitic batholites from Elba (Italy) have been shown to contain 2·67–3·36% of sodium expressed as Na_2O.[43] In the Ural mountains the possibility of using deposits of nepheline, sodalite and other minerals has been explored.[44] In Java, the Muriah volcano yields leucite-tephrites containing up to 3·66% Na_2O.[45] Samples of Kansas salt, used in a spectrographic search for minor elements, contained polyhalite and celestite.[46]

The occurrence of sodium in various natural waters has been investigated by a number of workers. Much of the work has been undertaken with a view to determining the geological origin of the water and for this purpose the results are frequently expressed as a ratio of concentrations of two ions e.g. sodium and potassium.[47-51] Eriksson has collected data on analyses of atmospheric precipitation and has compared the results with those for other natural waters. His work includes a bibliography.[52]

It has been shown that in cultivated plants sodium is present largely as the chloride and is in greatest quantity in the parts of greatest physiological activity.[53] The ash of Brazilian mangroves has been reported as rich in sodium, containing 20% Na.[54]

The sodium content of foods has been investigated. Flour contains 0·003% Na, and bread 0·660% Na;[55] most fruit contains less than 0·01g. per 100g., but tomatoes up to 0·035g. per 100g., while spinach, beet and carrots average 0·05g. per 100g.[56]

In the serum and plasma of blood 90% of the sodium present passes into the filtrate on ultrafiltration; that which remains is equal to the amount fixed in the proteins precipitated by ethyl alcohol.[57]

SECTION XXIII

THE PREPARATION AND USES OF SODIUM

By J.P. QUIN

THE LABORATORY PREPARATION OF SODIUM

When Mellor wrote the original Treatise metallic sodium, manufactured by the electrolysis of fused sodium hydroxide, was a common article of commerce, and at the present time Downs cell sodium, which attains the remarkably high degree of purity of 99•95%[1] is freely available on the market in the United Kingdom, the United States and many other countries. As might be expected, this material is suitable for all normal laboratory purposes, and it is therefore seldom that the preparation of metallic sodium in the laboratory need be undertaken.

However a number of methods for the formation and preparation of sodium on a small scale have been studied during the last thirty-five years and these are described in the following sub-section. Analytical figures showing the purity of the metal produced by the various methods are given where these are available. Unfortunately in many of the original papers the product is described as 'pure sodium' without the inclusion of any analytical data to justify the description.

In many cases some doubt has arisen as to whether a method of preparation should be dealt with as a laboratory preparation, or would be more appropriately discussed under the heading of manufacture. Much of the work, especially that published in the form of patents, has certainly been done with a view to the ultimate production of metal on the commercial scale. When, however, a method of preparation can be carried out by the use of ordinary laboratory techniques and there is no real evidence that the method has been attempted on the commercial scale, it has been considered for the purposes of this Supplement to rank as a laboratory process. Successful manufacturing processes, and what might be described as technological applications of chemical principles, are on the other hand dealt with under manufacture in a later sub-section (see page 323). It will be appreciated that some borderline cases are bound to occur.

FORMATION AND PREPARATION OF SODIUM BY CHEMICAL PROCESSES

In general it may be said that reactions whereby metallic sodium is produced by chemical processes involve (*a*) the thermal decomposition of sodium salts or (*b*) the thermal reduction of sodium compounds with metallic or non-metallic reducing agents. Since the advent of the electrolytic processes for the manufacture of sodium, however, comparatively little interest has been taken in the thermal production of the metal and, with the notable exception of the investigations of Hackspill and his collaborators, the amount of work carried out in this field in the last few decades has been small.

In an excellent survey of methods for the production of the alkali metals, Hackspill gives the following list of reactions which may be used to produce sodium or any of the alkali metals other than lithium.[2] Hackspill points out that many of the reactions are however of secondary or theoretical importance, and must be considered methods of formation rather than methods of preparation.

$$
\begin{aligned}
2MN_3 &= 3N_2 + 2M \\
2MCNO &= 2CO + N_2 + 2M \\
M_3Fe(CN)_6 &= Fe + 3MCN + 3CN \\
2MCN + Fe &= Fe + 2C + N_2 + 2M \\
4MOH + 3Fe &\rightleftharpoons Fe_3O_4 + 2H_2 + 4M \\
2M_2CO_3 + 2Fe &= Fe_2O_3 + CO_2 + CO + 4M \\
2MOH + Al &= MAlO_2 + H_2 + M \\
2MOH + 2Mg &= 2MgO + H_2 + 2M \\
2MCl + Pb &\rightleftharpoons PbCl_2 + 2M \\
2MCl + Ca &\rightleftharpoons CaCl_2 + 2M \\
2MCl + Ba(N_3)_2 &= BaCl_2 + 3N_2 + 2M \\
2MF + Fe &\rightleftharpoons FeF_2 + 2M \\
M_2SO_4 + Fe &\rightleftharpoons FeSO_4 + 2M \\
(2FeSO_4 &= Fe_2O_3 + 2SO_2 + \tfrac{1}{2}O_2) \\
6MOH + 4Fe &\rightleftharpoons 2Fe_2O_3 + 3H_2 + 6M \\
2MAlO_2 + Fe &\rightleftharpoons FeO + Al_2O_3 + 2M
\end{aligned}
$$

It is advantageous to work under reduced pressure, when the alkali metal is removed from the sphere of reaction in the gaseous form and condenses in the cooler portion of the apparatus.

It will be noted that in some cases the reaction is reversible. Thus, for example when sodium chloride is heated with iron under reduced pressure, reaction takes place according to the following equation:-

$$Fe + 2NaCl \rightleftharpoons FeCl_2 + 2Na,$$

and a mixture of metallic sodium, sodium chloride, ferrous chloride and iron is recovered from the cooler portion of the apparatus. The ferrous chloride, initially formed by the reduction of the sodium chloride with iron, is in part volatilized along with the sodium and the reverse reaction, whereby ferrous chloride and sodium react to give iron and sodium chloride, then takes place on cooling. If, however, the sodium chloride is replaced by sodium fluoride the ferrous fluoride formed by the reduction is only very slightly volatile and hence remains in the reaction chamber while the sodium metal distils off alone.

The list of reactions given above is not comprehensive, and in particular it is pointed out that a number of other metals can be used in place of iron when carrying out the reduction.

Thermal Decomposition of Sodium Salts.

Sodium is produced by the thermal decomposition of sodium salts such as sodium azide,[3-6] cyanide,[7] cyanate,[8] or ferrocyanide.[9]

Suhrmann and Clusius describe a method whereby sodium can be obtained in a high state of purity by the thermal decomposition of sodium azide.[3] The azide is allowed to decompose slowly by heating it under reduced pressure, not exceeding 0·1 mm. of mercury, over a period of three to four days. To initiate the decomposition it is necessary to attain a temperature of 275°C., but to ensure satisfactory evolution of nitrogen it is desirable to work at 280°C. In these circumstances the liberated sodium metal distils away from any residual mass in the decomposition vessel and may be suitably condensed. The yield of sodium is said to be 100%. It is claimed that the metal so produced is spectrographically pure and in particular is free from traces of gases such as hydrogen, and is therefore suitable for use in investigations on physical properties of sodium. Metal prepared in this way has been used for atomic weight determinations.[5] A possible mechanism of decomposition of sodium azide has been discussed.[6]

The thermal dissociation of sodium cyanide in an atmosphere of (*a*) helium at 600°C., 1000°C. and 1050°C. and (*b*) nitrogen at 1050°C., 1220°C. and 1225°C. has been studied.[7] It is shown that sodium carbide is formed in addition to sodium, carbon and nitrogen. This sodium carbide is turn largely dissociates into carbon and metallic sodium. The partial pressure of sodium at 1050°C. in a helium atmosphere above molten sodium cyanide is 117 mm. of mercury. In nitrogen the partial pressure of sodium over molten sodium cyanide at 1100°C. is 67 mm. When sodium cyanate is heated at 700°C. under reduced pressure decomposition takes place according to the equation:-[8]

$$2NaCNO \rightarrow 2CO + N_2 + 2Na.$$

Little work appears to have been done on the thermal decomposition of sodium ferrocyanide. When a mixture of sodium ferrocyanide and potassium ferrocyanide is heated under reduced pressure a sodium–potassium alloy distils off and forms large silvery drops which remain liquid at room temperature.[9]

Thermal Reduction of Sodium Compounds with Metals and Non-metals.

Little further work has been done on the preparation of sodium by the reduction of sodium compounds with carbon. Pinck has shown on a small laboratory scale that when a mixture of sodium carbonate and graphite is heated at 1000°C. under reduced pressure, a yield of sodium corresponding to 65% of the sodium content of the carbonate is obtained.[10] A number of processes for the manufacture of sodium by this route have been patented, however, and are discussed later (see page 324).

The preparation of sodium by the reduction of sodium chloride with calcium carbide has been studied.[11-17] The reaction, which proceeds according to the equation:-

$$2NaCl + CaC_2 \rightleftharpoons CaCl_2 + 2C + 2Na,$$

is reversible, and it is advantageous to work under reduced pressure or alternatively in a rapid current of inert gas which removes the sodium from the sphere of reaction as vapour. According to Hackspill the reduction proceeds in vacuo at temperatures above 800°C. with a yield of sodium of over 80% estimated on the calcium carbide.[2,11,12]

The reaction has been investigated at temperatures ranging from 600° to 1000°C. under a pressure of 1 mm. mercury [14-16] When the reduction is thus performed using a mixture of approximately 1 mol. of sodium chloride and $\frac{1}{2}$ mol. of calcium carbide, the results shown in Table I (see page 311). are obtained,[15] the yield of sodium being taken as the sodium actually produced, expressed as a percentage of the total metal available in the salt.

The use of excess of calcium carbide has no appreciable effect on the yield of sodium, but when the reduction is carried out under a pressure of 10 mm. of mercury the yield of metal is substantially reduced.

Beneficial effects are obtained by adding up to 10% of calcium fluoride to the reaction mixture of calcium carbide and sodium chloride, but substantially larger amounts of fluoride have an adverse effect on sodium production.[14] The presence of calcium oxide lowers the melting point or softening point of the mixture, but has no other advantage and diminishes the yield of sodium.[14] The product contains over 80% of sodium and less than 0·5% of carbon. The change in free energy ΔG° and the equilibrium constant K of the reaction:-

$$2NaCl + CaC_2 \rightleftharpoons 2Na + CaCl_2 + 2C$$

were calculated as shown below Table I on the next page.

TABLE I. - YIELDS OF SODIUM OBTAINED BY REACTION OF SODIUM CHLORIDE WITH CALCIUM CARBIDE

Time of reaction	Temperature of reaction	% Yield of sodium
½ hr.	700	0·7
	750	6·0
	800	17·2
	850	29·0
	900	35·8
1 hr.	600	-
	650	0·7
	700	2·3
	750	13·9
	800	25·8
	850	44·3
	900	79·0
2 hr.	650	0·9
	700	4·2
	800	45·4
	900	91·7

T°K.	700	800	900	1000	1100	1200	1300	1400	1500
ΔG°	26079	20342	14758	9311	4010	-1151	-6170	-11051	-15794
K	$7\cdot32 \times 10^{-9}$	$2\cdot8 \times 10^{-6}$	$2\cdot62 \times 10^{-4}$	$9\cdot26 \times 10^{-3}$	$1\cdot59 \times 10^{-1}$	1·62	$1\cdot08 \times 10$	$5\cdot29 \times 10$	$1\cdot99 \times 10^{2}$

The point of equilibrium where $\Delta G^\circ = 0$ is 1180°K. or approximately 900°C. It is claimed that these values agree quite well with the results obtained experimentally.

Russian workers have made a study of the reaction under very similar conditions.[17] They use intimate mixtures of finely ground sodium chloride and calcium carbide briquetted at a pressure of 50 kg. per sq. cm. The sodium chloride is heated for 30 minutes at 600–650° before use, and it is found that an excess of 0·1 mol. of sodium chloride is sufficient to ensure the optimum utilization of the comparatively expensive calcium carbide. When the reduction is carried out under a pressure of 4–5 mm. of mercury, the yield of sodium, calculated on the calcium carbide content of the mixture, reaches a maximum of 44% at 950°C. The ratio (γ) of the sodium metal produced to the amount of sodium lost through evaporation of the sodium chloride is 1·0, 0·7–0·8 and 0·5 at 900°C., 950°C. and 1000°C. respectively. The addition of 5% of calcium fluoride or sodium fluoride increased the yield and also the ratio (γ); the yield is considerably increased by working under reduced pressure. Thus a mixture containing 6% of sodium fluoride gives a yield of 75–82% under a pressure of 0·5 mm. The authors suggest that the presence of fluoride in the reaction mixture, besides lowering viscosity and so facilitating the reaction, is also beneficial in that it decreases the volatility of the sodium chloride. The sodium metal so obtained is in a more compact form that that obtained by working at higher pressures. The product contains 98·5% of sodium, 0·5% of silicon and up to 1% of iron. It is suggested that the iron content of the material is introduced accidentally when removing the sodium by scraping from the steel tube in which the reaction is carried out.

More recently the reaction has been studied at pressures less than 0·1 mm. of mercury with respect to the effect of temperature, time of heating, molar ratio of sodium chloride to calcium carbide, addition of sodium fluoride, purity of technical calcium carbide, and physical condition of the reaction mixture. It was found that when a mixture of sodium chloride and calcium carbide in the molar ratio 1:2 was heated for 1 hr. under a reduced pressure of 0·1 mm. of mercury, an 89% yield of sodium, based on the calcium carbide used, was obtained. The consumption of 65% calcium carbide was 1·57 g. per g. of sodium.[17a] The reduction of sodium chloride with calcium silicide according to the equation:-

$$2NaCl + CaSi_2 = CaCl_2 + 2Si + 2Na$$

has also been studied under similar conditions, and the effect of temperature, time of heating, molar ratio of sodium chloride to calcium silicide, and addition of calcium fluoride investigated. For 1 hr. at 900°C. with a molar ratio of sodium chloride to calcium silicide of 1:2 the consumption of calcium silicide was 94% and 3·4 g. of silicide was required to produce 1 g. of sodium.[17a]

Industrial processes based on the reduction of sodium compounds with calcium carbide have been proposed and are mentioned later (see page 325).

Sodium cyanide is a reducing agent and sodium may be formed by the reduction of metallic oxides with sodium cyanide in vacuo at temperatures ranging from 560°C., the melting point of sodium cyanide, to 750°C.[8,18] The metallic oxide is reduced to the metal with the simultaneous formation of metallic sodium together with carbon monoxide and nitrogen according to the equation:-

$$2XO + 2NaCN \rightarrow 2X + 2CO + N_2 + 2Na.$$

The secondary reaction:-

$$2CO \rightleftharpoons CO_2 + C,$$

also tends to take place.

When ferric oxide or nickel oxide is reduced with sodium cyanide, liberation of sodium occurs at temperatures approaching 700°C.[8] It frequently happens that alloy formation occurs between the metal produced by the reduction of the metallic oxide and the sodium simultaneously liberated. Thus lead oxide and tin oxide are quantitatively reduced at the melting point of sodium cyanide to yield alloys of sodium with lead and tin respectively. With barium and strontium oxides, reduction proceeds at 750°C. to give alkaline earth metal-sodium alloys. Calcium oxide, alumina and manganese dioxide are reduced by sodium cyanide only with difficulty and the reduction is said to be incomplete.[18]

The formation of sodium by reducing sodium compounds with barium has been discussed.[19] Potassium, cæsium or rubidium can be prepared by the thermal reduction of their compounds under reduced pressure with barium, which may conveniently be used in the form of barium azide. Barium azide decomposes between 100° and 200°C. to yield barium metal, which in turn reacts with the compound present to liberate the alkali metal which then distils off as vapour and may be suitably condensed. It is said, however, that owing to the comparatively high distillation temperature of sodium it is difficult to obtain a satisfactory yield of sodium by the barium azide route, and the method is accordingly not recommended for this purpose.

Sodium has been prepared by Hackspill's method whereby sodium compounds such as the chloride are reduced with metallic calcium under low pressure.[2,20,21] At ordinary pressures reduction is incomplete and the metal phase contains both calcium and sodium;[2] it is therefore necessary to separate these metals by distillation, preferably under reduced pressure. If, however, the operation is carried out at a sufficiently low temperature a pure product is obtained. At higher temperatures the metal is found to contain a small amount of calcium which is readily eliminated by a second distillation at 400°C. in glassware under reduced pressure. The preparation of sodium-calcium alloys by the reduction of sodium compounds with calcium is dealt with elsewhere (see pages 315, 325). It is claimed that the method produces very pure sodium which compares favourably with that obtained by other methods of preparation.

A modified form of the Hackspill method dispenses with the use of a high-vacuum pump, and uses a water pump only.[21] The reaction mixture is heated electrically to about 350°C. and when gas evolution ceases, as shown by a fall in the pressure to about 20 mm. of mercury, the water pump is isolated by closing a stopcock or sealing off at a constriction in the connecting tube. The sodium is then distilled off by gradually raising the temperature of the reaction mixture to 800°C. The yield of sodium is only slightly less than that given by the conventional Hackspill method. This modified Hackspill method would appear to provide a simple means of preparing small quantities of metallic sodium in the laboratory without the use of expensive apparatus.

The preparation of sodium by reducing sodium compounds with iron at low pressures and high temperatures has been studied by Hackspill and his collaborators.[2,10,18,22,23] Under reduced pressure the sodium produced is removed from the sphere of reaction as vapour, and it is accordingly possible to work at considerably lower temperatures than when using normal pressures. Thus under such conditions iron displaces sodium from sodium sulphate or arsenate at the melting points of these salts, and from sodium thiocyanate at 650°C.[10,23] Sodium cyanide is completely decomposed when heated with iron at 600°C., whereas sodium borate and metaphosphate require a temperature of 1300–1400°C. before sodium is liberated.[10,23]

In the case of sodium metaphosphate the reaction proceeds according to the equation:-

$$2NaPO_3 + 6Fe \rightarrow 6FeO + 2Na + 2P,$$

and phosphorus is formed in addition to sodium.[10] If, however, the reduction is carried out in the presence of silica, this compound unites with the sodium oxide content of the phosphate to give sodium silicate and in these circumstances only phosphorus and no sodium metal is produced at 1400°C.[10]

Sodium sulphide is reduced by heating with excess of iron in vacuo at about 1000°C. to give an almost quantitative yield of pure sodium metal.[10] This method of preparation has the advantage that it does not produce any volatile product other than metallic sodium. It is claimed that the addition of basic oxides such as calcium oxide to the reaction mixture has a beneficial effect and this has been the subject of a patent.[24] Iron reacts with sodium nitrate in vacuo at 600°C. to give sodium according to the equation:-[10]

$$2NaNO_3 + 4Fe \rightarrow 2Fe_2O_3 + N_2 + 2Na.$$

When sodium halides are heated in vacuo with iron at temperatures above about 800°C., sodium is formed.[10,22] With sodium chloride, bromide and iodide, however, a mixture of ferrous halide and sodium halide distils from the reaction mixture with the sodium vapour.[22] On condensation these halides contaminate the product and the ferrous halide and sodium tend to react to give iron and sodium halide. Sodium and iron fluorides, on the other hand, are much less volatile, and when sodium fluoride reacts with iron in vacuo at temperatures approaching the melting point of the salt, a good yield of sodium is obtained.[22]

Refs. p. 321

Some work has also been done on the decomposition of sodium hydroxide with iron and other metals in a current of nitrogen.[25] Thus when sodium hydroxide and iron are heated at 750°C., metallic sodium distils off and condenses in the cooler portions of the apparatus. At the same time some sodium hydride is formed and this material is likewise volatilized and condensed. When nitrogen containing a little hydrogen is used, only sodium hydride is formed, and as the hydrogen content of the nitrogen is progressively increased, a stage is reached when there is no deposit. It is suggested that in these circumstances the hydrogen reacts with the ferric oxide, initially formed by the reduction of the hydroxide with the iron, and the water so formed reacts in turn with the sodium. This may possibly explain[25] the poor yield given by the Gay Lussac and Thénard process[26] formerly used for the manufacture of sodium.

The reduction of sodium hydroxide with manganese in a current of nitrogen or hydrogen at 600°C. yields sodium, and the reaction proceeds rapidly at 700°C.: at the same time sodium hydride volatilizes and may be condensed in the cooler portions of the apparatus.[25] Ferromanganese and tungsten act in a similar manner, but with chromium a temperature of 800°C. is necessary before sodium is liberated. At 600–700°C. cobalt and nickel appear to produce traces of sodium vapour, but the nickel and cobalt are not oxidized, and no appreciable amount of sodium can be obtained by condensation.

Attempts to prepare sodium by the reduction of sodium hydroxide with zinc in a current of nitrogen or hydrogen were unsuccessful.[25]

Nickel is in general a poor reducing agent for sodium compounds and yields sodium only with sodium hydroxide and sulphide.[10,23]

When a mixture of sodium hydroxide and nickel is heated in vacuo, hydrogen evolution starts about 350°C., and at 600–650°C. metallic sodium is formed and distils off,[10] but the product is contaminated with sodium hydroxide which has been volatilized unchanged. If, however, the sodium hydroxide vapour is passed through a packed tower of powdered nickel at about 650–700°C. it is possible to attain complete reduction, and the product is pure sodium metal.[10]

Nickel does not reduce sodium cyanide, though mixtures of sodium cyanide and nickel heated in vacuo at about 900°C. yield a very small amount of sodium.[10] This is attributed to traces of oxide in the nickel which reacts according to the equation:-

$$2NiO + 2NaCN \rightarrow 2Ni + 2Na + 2CO + N_2.$$

Alternatively it is possible that the sodium cyanide might contain traces of sodium hydroxide. With pure iron-free nickel and pure sodium cyanide no sodium metal is formed.

When sodium sulphide is heated with nickel at about 1000°C. sodium is formed and distils off under reduced pressure,[10] but the yield of metal does not exceed 45%. Oxygen-containing compounds such as sodium carbonate or nitrate do not give sodium when heated with nickel in vacuo. At a sufficiently high temperature sodium oxide is produced and distils over unchanged.[10] Similarly nickel will not reduce sodium halides to form sodium.[10,23]

A disadvantage in reducing sodium compounds such as the chloride with carbon or calcium carbide is the evolution of carbon monoxide. This may be avoided by using, as the reducing agent, silicon or ferrosilicon in the presence of calcium oxide,[27,28] the reaction being:-

$$4NaCl + 4CaO + Si \rightarrow 2CaCl_2 + (2CaO),SiO_2 + 4Na.$$

The reactants, which should be dry, are pulverized, compressed into briquettes, and heated at 850°C. under a pressure not exceeding 250 microns, when the sodium distils off and deposits in a condenser which is preferably heated above the melting point of sodium. It is essential to use about three times the stoicheiometric amount of calcium oxide and 75% yields of sodium have been obtained.[27]

The reduction may also be carried out using an anhydrous sodium silicate in place of sodium chloride[29] at temperatures between 800° and 1300°C., when the sodium distils off and may be recovered by condensation.

The reduction of sodium compounds with potassium does not give sodium but a sodium-potassium alloy and is discussed elsewhere (page 316 and Suppl. 3)

The preparation of sodium may be carried out very conveniently by the thermal reduction of sodium compounds with powdered zirconium metal in vacuo.[30,32,33] The reduction mixture has the advantage of decomposing at not too high a temperature without the formation of any volatile product other than sodium, and the method has been recommended for the preparation of small amounts of sodium in situ for the determination of physical properties of the metal.

Thus a mixture of sodium dichromate and zirconium in the proportion 1:10 reacts smoothly at 250°C. in vacuo with the evolution of sodium.[30] The yield is about 50%, but the metal is contaminated with about 25% of oxide. When sodium chromate is used in place of dichromate the reaction starts about 740°C. and the yield of sodium is about 70%, with an oxide content of 30%.

Better results are obtained with sodium molybdate.[30] When mixtures of this compound and zirconium in the proportions 1:1 or 1:4 are heated in vacuo, the reaction proceeds smoothly at about 550°C., and whereas the 1:1 mixture gives a product containing a small amount of oxide, the 1:4 mixture gives a nearly quantitative yield of pure sodium.

Sodium tungstate likewise reacts readily with zirconium at about 450°C. in vacuo.[30] A 1:1 mixture of tungstate and zirconium gives sodium contaminated with oxide, but a 1:4 mixture gives an 80% yield of sodium free from oxide.

Other reducing agents have been proposed for the reduction of sodium compounds, and the preparation of sodium by reducing sodium sulphide with arsenic or tin[34] and sodium compounds with thorium[31] has been patented. A proposal to use ferrophosphorus as a reducing agent in the production of sodium from sodium carbonate is discussed later (see page 325).

The mechanism of formation of sodium by the reduction of sodium hydroxide with a number of metals including chromium, cobalt, copper, beryllium, tantalum, gold, silver, manganese, iron and ferrous alloys has been studied.[34a]

PREPARATION OF SODIUM ALLOYS BY CHEMICAL REACTION

When molten sodium chloride reacts with metallic calcium, reduction is incomplete and the metal phase produced contains both calcium and sodium. The equilibrium:-

$$2NaCl + Ca \rightleftharpoons CaCl_2 + 2Na$$

has been studied by Lorenz and Winzer who found that the metal phase contains over 99 atomic-% of sodium over wide ranges of temperature and of calcium chloride content in the fused salt phase.[35] Later work by Rinck, however, indicates that, depending on conditions of temperature and concentration of calcium chloride, the metal phase may contain substantial amounts of calcium.[36] By carrying out the reduction in the presence of molten metals such as lead[37,38] or antimony,[37] alloys of these metals with calcium and sodium may be obtained. The equilibrium is discussed in more detail elsewhere (see page 348).

The distribution equilibrium of sodium between molten sodium halides and molten metals such as lead, tin, antimony, cadmium, thallium, bismuth and gold has been studied.[37a]

The reduction of fused sodium compounds such as the hydroxide, fluoride, chloride, bromide or iodide with metallic potassium does not yield pure sodium but a sodium-potassium alloy.[36,39] With molten sodium chloride, the reduction has also been carried out in the presence of lead to give lead-sodium-potassium alloys.[40] The equilibrium in the fused state between potassium, sodium and their halides or hydroxides is discussed in greater detail under Potassium (see Suppl. 3).

The preparation of alloys of sodium with lead[40a] and mercury[40a-d] has been described.

ELECTROLYTIC METHODS OF PREPARATION OF SODIUM

Electrolysis of Aqueous Solutions of Sodium Compounds.

As might be expected, few attempts have been made to prepare sodium by the electrolysis of aqueous solutions of sodium compounds. It is claimed, however, that deposits containing appreciable amounts of free sodium metal have been formed by the electrolysis of sea water under special conditions.[41]

Electrolysis of Solutions of Sodium Salts in Non-aqueous Solvents.

A number of patents have been filed for the preparation of sodium by the electrolysis of solutions of sodium salts in non-aqueous solvents such as liquid ammonia or organic solvents, but there is no indication that such processes have found any technical application, and experimental work appears to have been confined to the laboratory or to comparatively small scale semi-technical operation.

In one process a solution of sodium chloride in liquid ammonia is electrolyzed using a permeable or semipermeable diaphragm and a metallic cathode which does not catalyze the formation of sodamide which tends to take place between the liberated sodium and the solvent, e.g. aluminium, magnesium, cadmium, zinc or tin.[42,43] The anode is of graphite, and the diaphragm of asbestos cloth or porous Alundum. During electrolysis the catholyte, which is an indigo blue solution of sodium in liquid ammonia, is separated from the anolyte and evaporated to give sodium metal. The product may be freed from contaminating sodium chloride by fusion.

Laboratory experiments carried out at Gersthofen, Germany, on the electrolysis of solutions of sodium chloride in liquid ammonia at −10°C. in a wrought iron autoclave which served as cathode, with a cylindrical graphite anode and a diaphragm, yielded sodium heavily contaminated with sodamide.[44] The sodium and the chlorine formed during electrolysis reacted with the solvent as follows:-

$$2Na^+ + 2NH_3 \rightarrow 2NaNH_2 + H_2$$
$$6Cl^- + 8NH_3 \rightarrow 6NH_4Cl + N_2.$$

The evolved gas was a mixture of about 75% of hydrogen and 25% of nitrogen. The efficiency depended on the adoption of a suitable diaphragm. Cotton diaphragms were found to be unsuitable; asbestos cloths and ceramic diaphragms were also tried, and with the latter current efficiencies of up to 80% were obtained in the production of sodamide. It would therefore appear that the process is suitable for producing sodamide rather than metallic sodium.

During the operation of the cell it was found that a considerable increase in voltage took place in the course of a few hours. This was caused by clogging of the diaphragm pores with sodamide, and is most severe when the current density is highest, probably because then the amount of ammonia entering the cathode compartment is no longer sufficient to dissolve the precipitated sodamide. Continuous operation is therefore not possible.

A patent proposes to carry out the electrolysis using a solution of sodium chloride in a solvent mixture of liquid ammonia and an inert organic solvent, in which liquid ammonia is soluble but sodium is substantially insoluble.[45] The organic solvents are selected from a group comprising dioxan, alkyl ethers of molecular weight not exceeding 75, alkyl amines of molecular weight not exceeding 75 and benzene. The organic liquid is present in such amounts that a sodium-rich phase is formed by solution of the alkali metal, produced by electrolysis, in the solvent mixture.

Production of sodium by electrolysis of solutions of anhydrous sodium salts in liquid ammonia and methylamine, ethylamine or pyridine, has also been the subject of a patent.[46,46a] The concentration of the sodium salt in the electrolyte should exceed two molar parts, and the sodium is produced as a colloid, a suspension, a paste, or as a deposited metal, depending on the salt concentration. The electrodes may be of carbon and iron, and the cell operates at current densities ranging from 10 to 100 amp. per sq. dm. Refrigeration is recommended to avoid excessive evaporation of ammonia.

Sodium may also be produced by the electrolysis of a solution of sodium acetylide in liquid ammonia.[47] The sodium so liberated dissolves in the ammonia giving a localized blue colour in the vicinity of the cathode. Small amounts of gas and carbon are produced at the anode. The mechanism of the explosion which occurs after the liberation of sodium during the electrolysis of sodium nitrate in liquid ammonia has been investigated.[47a]

The deposition of sodium from solutions of sodium salts in non-aqueous solvents other than liquid ammonia has also been studied.[48-51]

Work has been reported on the preparation of sodium by the electrolysis of solutions of mixtures of sodium chloride with aluminium chloride or of sodium bromide with aluminium bromide in nitrobenzene and in mixtures of nitrobenzene and xylene.[48,49] With nitrobenzene, a low current density and the use of a diaphragm are recommended.[49] When nitrobenzene and xylene are used, the preferred solvent mixture is one part of xylene to two parts of nitrobenzene, and optimum results are obtained with a current density of 1 amp. per sq. dm., when a solid smooth deposit of sodium with a metallic lustre is obtained. This method of preparation would appear to be applicable to the production of small amounts of sodium in the laboratory.[48]

Attempts to prepare sodium by electrolyzing solutions of sodium iodide or sodium thiocyanate in anhydrous pyridine were unsuccessful.[50]

Electrolytic studies have been made on solutions of sodium chloride, sulphate and nitrate in fused ethylpyridinium bromide, which for this purpose may be regarded as a non-aqueous solvent, although it might with equal propriety be described as a fused salt. All these sodium salts were found to have a very low solubility in ethylpyridinium bromide at about 135°C. and no sodium was obtained by the electrolysis of such solutions.[51]

The electrolytic deposition of sodium from non-aqueous solutions at normal temperatures has been discussed.[51a,b]

Electrolysis of Sodium Compounds in Non-aqueous Solvents Using a Sodium Amalgam Anode.

A novel method for the preparation of sodium was patented by Ewan in 1923,[52,53] by which sodium is obtained by electrolyzing a solution of sodium cyanide in anhydrous liquid ammonia, using a sodium amalgam anode. The operating temperature is maintained between the boiling point and the freezing point of the electrolyte, and the concentration of sodium cyanide in the electrolyte is such that during electrolysis the solution forms two layers: an upper layer, remote from the anode, which contains the sodium, and a lower layer in contact with the amalgam which contains the sodium cyanide in the dissolved state.

The Ewan process has been studied in Germany on the laboratory scale[44] using a two-litre autoclave, and it was found that the voltage seldom exceeded 1·7V. It was also found that when the electrolysis is carried out using an iron cathode, substantial amounts of sodamide are deposited on the cathode as a firmly adhering crust which is very difficult to remove, and that the hydrogen formed contains over 20% of nitrogen. Moreover, small amounts of a highly explosive substance, presumed to be mercury azide, are formed on the anode. These operational difficulties may serve to explain why this interesting process does not appear to have attained any success on the commercial scale.

The preparation of sodium by the electrolysis of solutions of sodium salts in ethylenediamine, using a sodium amalgam anode, has been studied.[44,54-56]

Russian workers electrolyzed solutions of sodium bromide in ethylenediamine at temperatures over 100°C. using a sodium amalgam anode, at current densities varying from 1·4 to 9·0 amp. per sq. dm., but obtained only very small quantities of sodium at low current efficiency.[54] Most of the experimental results are reprinted in an American paper on the subject.[55]

A reinvestigation of the problem by German workers showed that complete dehydration of the ethylenediamine is essential, in order to prevent the formation of sodium hydroxide which is precipitated as a slimy deposit and interferes with efficient electrolysis.[44] To achieve the requisite degree of dryness, it is necessary to rectify the solvent over metallic sodium for several hours, and this results in losses owing to polymerization. In addition considerable polymerization losses occur during the electrolysis, which, it is said, must be carried out near the boiling point of ethylenediamine (116°C.). No efficiency figures are given for the production of sodium in this way.

Better results appear to have been obtained by Putnam and Kobe, who state that it is essential to maintain the operating temperatures at or below the melting point of sodium in order to avoid reaction of that metal with the solvent. In a typical experiment 10 c.c. of a solution containing 25% of potassium iodide and 5% of sodium iodide was electrolyzed in a 20 c.c. test tube, using a 0·5% sodium amalgam anode, a copper cathode of 5 sq. cm. immersed area, and a current of 0·5 amp.; the cell is held at 100°C. during the electrolysis by immersion in a water bath. Pure sodium is said to be liberated at current efficiencies exceeding 90%. No analytical figures for the purity of the sodium are given, however, and in particular the potassium and mercury contents of the metal are not stated. The method appears to offer a convenient laboratory method for the preparation of sodium. A detailed description is given of the method adopted for the purification of the ethylenediamine.[55]

Electrolysis of Fused Sodium Compounds.

The preparation of sodium by the electrolysis of fused sodium hydroxide and fused sodium chloride is discussed in detail elsewhere (see pages 328, 332). These processes do not appear to lend themselves to convenient operation on the small scale, and very little information has been published about the laboratory preparation of sodium in this way. A miniature electrolytic cell for the preparation of small quantities of alkali metals has been described. The cell comprises a $1\frac{1}{2} \times 3$ in. graphite crucible into which is inserted a 1×3 in. alundum thimble to act as cathode compartment and diaphragm, and a cathode of $\frac{3}{16}$ in. stainless steel, and is heated externally. Work on other alkali metals suggests that sodium chloride would provide a suitable electrolyte. The molten metal produced by the electrolysis is withdrawn from the cell by means of a stainless steel pipette.[56a]

The production of sodium by the electrolysis of fused sodium cyanide has, however, been satisfactorily carried out in the laboratory.[57] When fused sodium cyanide is electrolyzed, using a graphite anode and a 1 mm. diameter nickel wire as cathode, sodium is liberated at the cathode in the form of molten drops which rise to the surface of the electrolyte and form a comparatively thick layer above it. The cell operates with a current of 2·5 amp. at 6 V., and sodium is obtained with 90–95% efficiency. Nickel, copper and iron cannot be used for the anode, as these metals dissolve in the fused cyanide. Cyanogen is liberated at the anode during electrolysis, and this may be collected and absorbed in a solution of sodium hydroxide or sodium carbonate, the sodium cyanide so produced being returned to the process at a later stage, after being rendered anhydrous.

The electrolysis of a fused aluminium fluoride–sodium fluoride, AlF_3,-$3NaF$, at 1010°C. with a water-cooled iron cathode gave sodium which contained only a small amount of aluminium. When the cooling is sufficient, it is possible to reduce the amounts of aluminium produced to very small proportions. If a graphite cathode is used, without cooling, then aluminium only is produced.[57a]

It is sometimes found that the sodium formed by the electrolysis of a fused sodium salt enters into secondary reactions with the electrolyte with the result that the product of the electrolysis is not pure sodium but a sodium compound or compounds, which may, however, contain some free metallic sodium.

Thus the preparation of sodium by the electrolysis of fused sodium nitrite has been attempted, but the metal initially formed during the electrolysis enters into a secondary reaction with the electrolyte and the final product is not sodium but sodium compounds.[58] It might be expected that the electrolysis would proceed according to the following equation with the liberation of free sodium, $NaNO_2 \rightarrow Na + NO_2$. Experiments in Pyrex glass apparatus using iron electrodes showed, however, that the sodium liberated at the cathode reacted with the fused nitrite to form sodium monoxide and gaseous nitrogen, while the nitrogen dioxide produced at the anode likewise reacted with the electrolyte to yield sodium nitrate and nitric oxide, and it was only after some time that the concentration of nitrate in the vicinity of the anode became sufficiently high to permit part of the nitrogen dioxide to be liberated from the bath.

Similarly when fused sodium metaphosphate is electrolyzed using a nickel cathode and an iron anode, the sodium produced at the cathode reacts with the fused electrolyte, liberating phosphorus, and forming sodium orthophosphate.[59] At the anode, the following reaction takes place with the formation of phosphorus pentoxide and oxygen: $2PO_3 \rightarrow P_2O_5 + \frac{1}{2}O_2$.

When molten borax is electrolyzed at about 800°C. in a graphite crucible using an internally cooled iron cathode, the metallic deposit on the cathode consists of an inner layer of sodium, a middle layer of sodium and boron, and an outer layer of boron.[60] It is suggested that the sodium produced by the electrolysis tends to react with the fused electrolyte to produce boron, and it is found that increase in the temperature of operation diminishes the yield of sodium and increases the formation of boron. The addition of slightly soluble oxides, such as aluminium oxide or beryllium oxide, is found, however, to prevent reduction of the electrolyte by the sodium almost completely.

A study of the electrolysis of fused systems containing sodium aluminate with cryolite or sodium fluoride has shown that under suitable conditions sodium may be formed.[60a]

Small amounts of highly pure sodium may be prepared by electrolysis through glass.[61-65] When an evacuated glass electric light bulb is partially immersed in a molten sodium compound and a current passes between the filament and an electrode in the molten salt, electrons emitted from the filament are carried to the glass wall and there neutralize sodium ions in the glass, which thus becomes atoms. These are evaporated by the heat and are deposited on the cooler portions of the bulb. Sodium ions from the molten salt replace those of the glass and migrate through it, being in turn neutralized at the inner surface. It is possible under suitable conditions to deposit about 300 mg. of sodium per hour with a 60 W., 110 V. Lamp.[64] Neither potassium nor lithium ions are transported in this way, and the sodium deposited is therefore spectroscopically extremely pure, the potassium present not exceeding 2 p.p.m.[64]

The formation of dendrites of sodium during the electrolysis of glass has been studied.[64a,b]

Theoretical considerations underlying the electrolysis of fused sodium salts have been discussed.[66,67]

Electrolysis of Sodium Compounds in Fused Electrolytes Using a Molten Metal Anode.

The preparation of sodium by the electrolysis of a fused mixture of sodium hydroxide, bromide and iodide, using a molten sodium amalgam anode, has been developed on the technical scale and is discussed under the manufacture of sodium from sodium amalgam. It has been proposed to prepare sodium from a molten alloy of sodium with tin or other metal of similar properties, by electrolyzing a melt consisting chiefly of sodium borate using the molten alloy as anode.[68]

PREPARATION OF SODIUM ALLOYS BY ELECTROLYSIS

The preparation of sodium amalgam by electrolysis of aqueous solutions of sodium chloride in the presence of a new mercury cathode is discussed elsewhere (see Volume II, Supplement 1, pages 299, 307; see also Mellor, IV, 1013). The concentration of sodium amalgam by evaporation of the mercury content is described later (see page 327).

Attempts to prepare substantially pure sodium by the electrolysis of fused mixtures of sodium hydroxide and potassium hydroxide using a sodium amalgam anode were unsatisfactory as the sodium metal so produced contained a considerable amount of potassium, and the method is therefore more suitable for the preparation of a sodium-potassium alloy.[44]

The preparation of metallic sodium in the form of a lead–sodium alloy obtained by electrolyzing molten sodium chloride using a molten lead cathode has been investigated on the laboratory scale in Germany.[69] Electrolysis is carried out at about 850°C. in an extremely heated nickel crucible at 4.5V., using a molten lead cathode in which the liberated sodium dissolves, and a graphite anode at which chlorine is discharged. Alloys containing up to 25–30% of sodium can be prepared with a current efficiency of approximately 100%. At lower temperatures the absorption of sodium in the lead is less complete, and this is attributed to the reduced rate of diffusion of the sodium initially deposited on the surface of the molten cathode. Temperatures higher than 850°C. are inadvisable as the molten salt then shows a tendency to evaporate. Crucibles of porcelain or graphite are rapidly attacked by sodium, and welded iron crucibles tend to leak at the welds. The use of electrolytes containing fluorides, which melt at temperatures down to 500°C., has also been considered. The process has been used on the commercial scale for the manufacture of lead-sodium alloy and is discussed later (see page 353).

Sodium–lead alloys are produced by the electrolysis of a mixture of 7 parts of sodium chloride, 2 parts of sodium fluoride and 1 part of potassium fluoride at 600°C., using a molten lead cathode.

Refs. p. 321

When electrolysis is carried out for 10 hr. at 10–15 V. using a graphite anode, a sodium–lead alloy containing only 0·8% of sodium is obtained at poor current efficiency. Better results are obtained when potassium bifluoride or ammonium bifluoride was substituted for potassium fluoride in the melt, and in these circumstances it proved possible to obtain alloys containing 2% of sodium.[69a]

Lead–sodium–potassium alloys have been prepared by the electrolysis of a fused mixture of sodium and potassium chlorides using a molten lead cathode.[70] Ternary alloys of sodium and barium with tin, antimony and bismuth have been prepared by electrolyzing fused mixtures of sodium and barium chlorides with a molten metal cathode of tin, antimony or bismuth[71] and ternary alloys of sodium and calcium with antimony and bismuth have been similarly obtained from fused mixtures of sodium and calcium chlorides.[71]

Sodium has been isolated in the form of a sodium–lead alloy by the electrolysis of molten sodium cyanide, with or without sodium halides, using a lead cathode and a carbon anode.[71a] A sodium–mercury alloy has been prepared by electrolysis of a fused melt containing 46% of sodium hydroxide, 27% of sodium bromide, 18% of sodium iodide and 9% of sodium cyanide in the presence of a mercury cathode at 280°C. Glass vessels are rapidly attacked by the melt but sintered alumina is satisfactory.[71a]

The preparation of sodium–calcium alloys in the Downs cell is described later (see page 340).

THE MANUFACTURE OF SODIUM

Sodium was originally manufactured by reducing sodium compounds with suitable reducing agents at high temperatures, but in 1890 Castner applied for a patent for producing the metal by electrolysis of fused sodium hydroxide and by 1893 was making sodium on the commercial scale at Oldbury, England, at the rate of about two tons per week.[1]

The ease and simplicity of the Castner process offered very considerable advantages over the older high temperature processes, which consequently become obsolete in a very short time. The Castner cell rapidly attained considerable commercial success and as such, or in a slightly modified form, was soon operating in Germany, Norway, Italy, France, Japan and the United States.[2]

Until the middle of the nineteen twenties the Castner process was to all intents and purposes the only practical method of manufacturing sodium, and in 1926 the world production of sodium by this means reached a peak of 15,000 tons. This was before the use of sodium in the manufacture of tetraethyl lead caused a considerable rise in world production.[3]

However, about this time the Downs process for the manufacture of sodium by the electrolysis of fused sodium chloride was successfully developed in the United States and since then the Castner process has been gradually superseded. Castner cell sodium is no longer made in England or the United States, but a Castner process was working in France up to 1940 and the cell was still in operation in Japan in 1954.[3] In 1944 the German Castner capacity was 160 metric tons per month.[4]

The Castner process is now unlikely to be established in a new works unless the required quantity of sodium must be made 'on the spot' and is insufficient to warrant the erection of Downs cells which have a comparatively large output.[3]

In the United Kingdom the first Downs plant was installed in 1937, and since then other plants have come into operation. Before the second world war there were two producers in Germany.[2] Degussa operated Downs cells with a total capacity of 650 metric tons per month, and I. G. Farbenindustrie used Castner cells having a total capacity of 80 metric tons per month but operated at a low output.[4]

The following estimated outputs of sodium are given for 1954:-[2]

	Tons per Annum
Western Germany	8,000
France	3,000
Italy	No figures available
Japan	2,500

The total capacity of the sodium plants in the United States in 1954 was approximately 300 million pounds per year, and the output of sodium in 1952 was 123,187 tons and in 1953 120,481 tons.[5]

The following figures given for the estimated world production of sodium illustrate the growth of the demand for the metal.[2]

Refs. p. 326

Year	Estimated World Production Tons	Castner	Downs
		% of total output	
1900	1000–2000	100	-
1910	11,000	100	-
1920	12,500	100	-
1930	18,000–20,000	50	50
1940	73,000	15	85
1952	140,000	5	95

In an estimate published in 1957 the world production of sodium is given as about 300 million lb. annually, about 260 million lb. of this being produced in the United States. The largest American producer is the Ethyl Corporation with plants at Baton Rouge, Louisiana, and Pasadena, Texas. The second largest producer is Du Pont with a plant at Niagara Falls, N. York, and a second plant scheduled to go into production at Antioch, California, in 1957. The third largest producer is National Distillers Products Corp. with a plant at Astabula, Ohio, built in 1951 and now being expanded. The repective capacities of these three producers are about 120, 100 and 40 million lb. of sodium per year.[6a]

Small tonnages of sodium have also been made by other processes. Thus, for example, the Ciba process[6,7] which operates in Switzerland was producing 500 tons per year in 1926.[7] No recent figures appear to be available for Ciba cell production however. A number of reviews describing the development of the manufacture of sodium metal give more detailed information on this subject and some have extensive bibliographies.[1-3,8-15c]

THE MANUFACTURE OF SODIUM BY THERMAL PROCESSES

No evidence has been found that the manufacture of sodium has been carried out by thermal reduction on any significant scale during the last thirty five years. The metal was at one time made by reducing sodium compounds with carbon, but the successful development of the electrolytic routes to the metal rendered all other methods of production obsolete. It is, however, possible that the manufacture of sodium by chemical means may still prove attractive in localities where it is essential that the metal is made on the spot and where no electrical power supply is available.[3] It has in fact been suggested that an improved Deville method of manufacture, whereby sodium is distilled from a fused mixture of sodium carbonate and carbon, could produce cheaper sodium than an electrolytic process,[16] and in recent years a number of patents covering thermal routes to the metal testify to a continued interest in this subject.

Thus, patents have been granted for processes for sodium manufacture involving the reduction of sodium compounds such as the carbonate or hydroxide[17-20] or borax[21] with carbon. In the former case the reduction may be carried out under reduced pressure,[18-20] while in the latter sodium is evolved at a temperature of 1000–1200°C., and is recovered by condensation, followed by sublimation of boric oxide at 1300–1400°C. A recent patent describes a process whereby molten sodium hydroxide reacts with carbon at 800–950°C. while a stream of hydrogen or inert gas is passed through the mixture. Hydrogen is the preferred gas as it gives the best yield of sodium (approx. 85%). The gas pressure is approximately atmospheric and the amount of sweeping gas is about 4–5 times the amount of hydrogen formed by the reaction:-[20a]

$$6NaOH + 2C = 2Na + 3H_2 + 2Na_2CO_3.$$

In one method of manufacture, sodium carbonate is reduced with carbon in a high-temperature reactor to produce sodium vapour and carbon monoxide. The sodium vapour is condensed to give liquid sodium and a dross consisting of sodium carbonate and carbon. The sodium is separated from the dross by fluxing with sodium hydroxide. The flux is then contacted with carbon monoxide at a temperature of at least 318°C. when sodium carbonate is produced. The treated flux is then recycled to the reactor.[20b] Patents have also been granted for a method of producing sodium metal in which sodium chloride or sulphate is mixed with a non-volatile base such as calcium oxide and a reducing agent such as coke, and then heated in an induction furnace under reduced pressure in an inert atmosphere to a temperature at which the liberated sodium distils off, and may be recovered by condensation.[22-25]

Some attention has been directed towards the development of thermal processes, in which the sodium vapour produced is rapidly condensed and removed from the admixed gases, such as carbon monoxide, formed as by-products during the reduction.

In one such process the carbon monoxide and sodium vapour mixture, produced by reducing sodium carbonate with carbon, is diluted with a cooling gas such as carbon monoxide in order to condense the sodium as liquid metal.[26] In another process a mixture of sodium carbonate and carbon is introduced into a furnace at 1200°C., or above, at a pressure of 0·5 atm.[27] The mixture of sodium vapour and carbon monoxide evolved is expanded to a reduced pressure of 0·4–4 mm. of mercury, and rapidly chilled at 375–400°C. by means of a quenching liquid which is a sodium–lead alloy containing 5–15% of sodium. Part of the quenching liquid is withdrawn continuously into a still at a temperature of 600°C. whence the sodium is recovered by distillation, presumably at reduced pressure. Other quenching liquids, such as volatile metals miscible with sodium, molten salt mixtures and heavy oils, may also be used. It is claimed that this method of preparation produces sodium at good efficiency with a high rate of working.

Another patented process recovers sodium from gases containing sodium vapour by absorbing the metal in molten tin at temperatures varying between 900°C. and 1200°C.[28,28a]

A patent has been granted for a process in which sodium vapour produced by reducing sodium carbonate with carbon at 1100°–1200°C. is condensed by molten sodium metal at 110°–150°C. Molten lead can also be used as a cooling liquid and in these circumstances a sodium–lead alloy containing up to 28% of sodium may be obtained.[29]

A number of patents relate to proposed processes in which sodium chloride is reduced with calcium carbide.[30-34] The reaction may be carried out under reduced pressure,[31,32] or in a current of inert gas.[33] The use of a cooling gas to promote condensation of the vapour to liquid metal has been proposed.[34]

Sodium may also be prepared from sodium chloride by passing the vaporized chloride through a heated zone at a temperature between 800–1100°C. containing solid calcium carbide, at a pressure substantially less than atmospheric, whereby the sodium chloride is reduced and metallic sodium vapour produced. The sodium vapour is then condensed and recovered.[33a,b]

Ferrophosphorus has also been proposed as a reducing agent for sodium carbonate or hydroxide. A caked or briquetted mixture of finely ground ferrophosphorus and the sodium compound is heated at 900°–1500°C. under reduced pressure, and the gaseous products quickly removed from the reaction vessel and rapidly cooled to separate the sodium metal from the other gaseous products. Condensation of the sodium may be brought about by introducing a spray of cooled mineral oil.[35] The reduction of sodium chloride with silicon in the presence of lime has been tried out on a comparatively large scale and a 2000 lb. batch has been reduced in 24 hr. giving a 75% yield of sodium.[36]

The manufacture of sodium by reduction of sodium aluminate with metallic aluminium at a temperature above the melting point but below the boiling point of aluminium has been patented.[36c]

The reduction of sodium ferrite[36a] and sodium silicate[36b] with iron has been the subject of patents.

THE MANUFACTURE OF SODIUM ALLOYS BY THERMAL MEANS

The preparation of sodium alloys by thermal means has been the subject of a number of patents.[37-40]

A metal compound other than an alkali metal compound, e.g. a mercury or lead salt, is treated with a solution of an alkali metal addition compound of an organic compound, such as a sodium naphthalene addition compound, to effect production of a sodium–lead alloy or a sodium–mercury alloy.[38]

Sodium–lead alloys are produced by heating sodium and lead to form a molten mass which is protected by a flux of 3 parts of potassium hydroxide and 2 parts of sodium hydroxide or other material which will not contaminate the alloy.[39]

MANUFACTURE OF SODIUM FROM MERCURY CELL AMALGAM

Sodium amalgam produced by the electrolysis of brine in a mercury type cell represents a cheap potential source of sodium metal, and it is therefore not surprising that some attention has been directed towards the utilization of brine cell amalgam as a raw material for the manufacture of sodium.

Sodium is in fact obtained very simply from sodium amalgam by the removal of the mercury content of the amalgam by distillation, and as long ago as 1903 an apparatus was patented for carrying out this process continuously.[1] The amalgam was tapped from a brine cell, distilled to leave a residue of metallic sodium, and the vaporized mercury returned to the cell after condensation for further enrichment by electrolysis. The preparation of sodium in this way suffers from the serious disadvantage that the sodium content of brine cell amalgam is low and the weight of mercury which has to be evaporated per unit weight of sodium is therefore very large indeed.

In order to avoid this it has been proposed to operate a mercury cell at a sodium concentration in the amalgam sufficiently high to permit the recovery of a solid alloy, $NaHg_3$, on cooling the amalgam. Thus by operating at a temperature above 70°C. the sodium content of the amalgam may be permitted to rise to 1%, which corresponds to its solubility at this temperature. On cooling to 0°C., where the solubility is about 0·5%, about half the sodium can be recovered by filtering out the solid crystals of $NaHg_3$. The filtrate is then reheated and recycled to the electrolysis cell. Metallic sodium is recovered from the $NaHg_3$ by distilling off the mercury in a retort. It has been pointed out, however, that when the sodium concentration in the amalgam is allowed to exceed about 0·2 to 0·3%, the current efficiency of the mercury cell falls off, hydrogen is evolved in dangerous amounts along with the chlorine, and other difficulties in cell operation are encountered.[2]

A process has been patented whereby sodium is prepared from amalgam without the necessity of operating the mercury cell at high sodium concentrations.[2-5c] In order to ensure optimum electrolytic operation the mercury cell is run at the usual amalgam concentration of about 0·2% of sodium. This amalgam is then withdrawn from the cell and concentrated to about 0·34% of sodium in a multi-effect evaporator using mercury vapour as a heating medium. The partially concentrated amalgam is then concentrated to about 50% of sodium in a mercury boiler. It will be noted that the melting point of 50% sodium amalgam is approximately 42°C. It is claimed that by operating the boiler on a continuous basis it is possible to avoid the formation of the high-melting intermediate amalgams, such as $NaHg_2$ with a melting point of 354°C. The 50% sodium amalgam is then distilled in a retort to give metallic sodium, and mercury which is recycled. It should be remarked that sodium made from amalgam contains small amounts of mercury as an impurity.

Recent patents[6-6b] propose to recover sodium from sodium amalgam by first increasing the sodium content of the amalgam to 10% and preferably to 40–60% by weight, by distillation. The concentrated amalgam is then treated with solvents such as liquid ammonia, ethylenediamine, methylamine or fused sodium hydroxide. Thus sodium may be extracted from concentrated amalgam by treatment with fused sodium hydroxide at temperatures between 325° and 600°C., and by the addition of substances such as sodium carbonate, potassium hydroxide, sodium bromide or sodium iodide, the minimum temperature may be reduced below 325°C. Extraction of the sodium from the concentrated amalgam is simplified by the inversion of the two liquid layers, the concentrated amalgam floating on the fused hydroxide and sinking below it as denudation proceeds. It is said that the sodium may be recovered from the hydroxide solution by raising its temperature (see page 335).

ELECTROLYSIS OF FUSED SODIUM COMPOUNDS USING AN AMALGAM ANODE

The Gilbert Process.

The production of metallic sodium by the electrolysis of a solution of a sodium salt in anhydrous liquid ammonia using a liquid sodium amalgam anode, as proposed by Ewan,[7] does not appear to have been operated on the commercial scale, but a process devised in America by Gilbert on somewhat analogous lines seems to have been more successful and has reached the pilot plant scale.[8-18]

In the Gilbert process sodium is prepared by the electrolysis of fused sodium hydroxide, which may or may not contain other sodium salts, in the presence of a liquid sodium amalgam anode. Little information is available as to the development of the process in America. In Germany, however, the process was developed by the I. G. Farbenindustrie immediately prior to, and also during, the 1939–45 war, and a considerable amount of information has been published on the design and operation of a pilot plant at Gersthofen, near Augsburg.[18] This plant consisted of a 1000 amp. cell having revolving metal discs which picked up a thin film of sodium amalgam, and so acted as the anode. The cell, shown diagrammatically in Fig. 1, operates at low voltage and good current efficiency. A brief description of the design and operation is given below. Table II gives a summary of the design and operating data for the 1000 amp. cell and also for a proposed 16,000 amp. cell.[18]

The cell has four principal parts, viz. the lower, middle and upper sections, and a rotor. The lower section is a semi-circular well containing the rotor, consisting of three nickel discs carried by a shaft entering the well through a combined packing gland and bearing on one side, and supported by a bearing block on the opposite side. The packing is graphitized asbestos and oil. Two cast iron displacers fitted between the discs reduce the mercury capacity of the cell. The amalgam enters through an inlet pipe and amalgam trap at one side of the cell, and leaves through a similar trap and outlet pipe at the opposite side of the cell. Anode bus bars are fitted to the section and the well has a jacket through which heated oil is circulated to maintain a temperature of 230–250°C.

The middle section serves as insulation between the cathodic top section

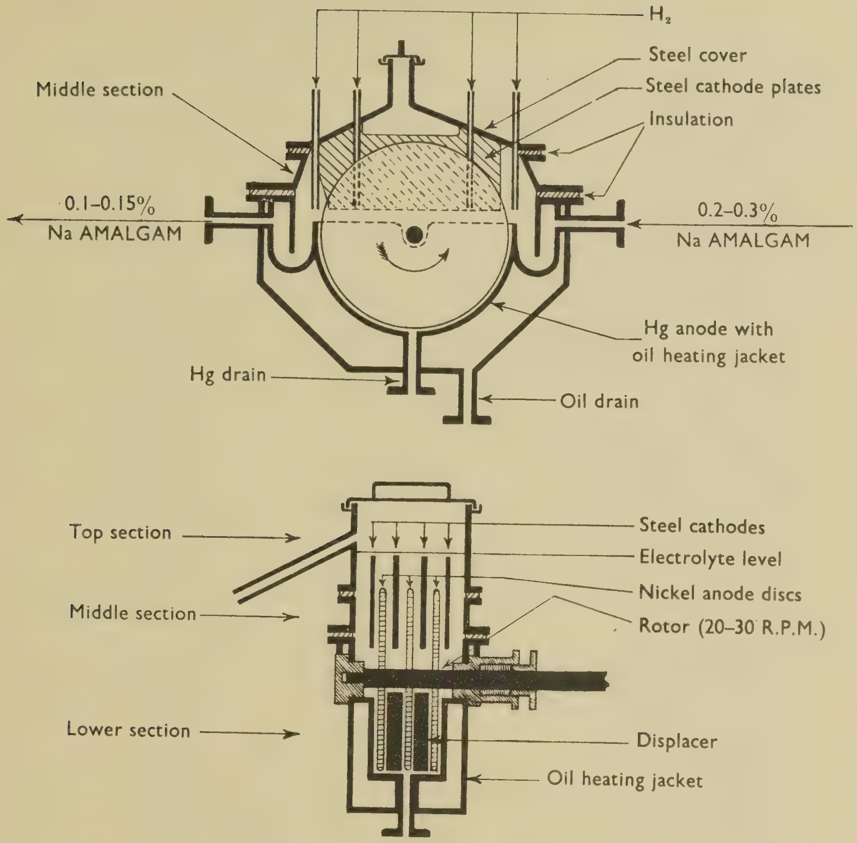

FIG. 1. I. G. FARBENINDUSTRIE 1000 AMP. EXPERIMENTAL VERTICAL SODIUM CELL

and the anodic lower section. The top section carries the nickel cathode connexions, two pipes for introducing hydrogen into the melt, an overflow for the sodium metal and a readily removable cover. There are two cathodes centred between the three anode discs, and two cathodes on the outer side of the two outer anode discs.

The cell is filled with a molten mixture of 53% of sodium hydroxide, 28% of sodium bromide and 19% of sodium iodide: this electrolyte can be used at temperatures down to 230°C.[17] The cell is run in conjunction with a mercury-type chlorine cell the amalgam from which is pumped to a constant head tank, where the stream is divided into two parts, one going to the sodium cell, and the other to the amalgam denuder of the chlorine cell. The amalgam stream to the sodium cell, preheated in a heat exchanger by means of the semi-denuded amalgam returning from the sodium cell,[18] is then further heated to 250° C. The amalgam is passed through the cell at such a rate that the sodium concentration on entering and leaving the cell is 0·2–0·3% and 0·1–0·15% respectively, so that it is denuded of only about one half of its sodium content, after which it is returned to the chlorine cell denuder where the residual sodium is decomposed with water to give a ·50% sodium hydroxide. It is desirable to introduce the amalgam near the surface of the pool of amal-

Refs. p. 332

TABLE II. - OPERATING DATA FOR THE GERSTHOFEN SODIUM AMALGAM CELLS

	1000 amp. cell	16,000 amp. cell
Daily production of sodium (85% efficiency)	18 kg.	285 kg.
% Sodium in amalgam entering sodium cell	0·2–0·3	0·2–0·3
% Sodium in amalgam leaving sodium cell	0·1–0·15	0·1–0·15
% Mercury in sodium metal	0·5–1·0	0·5–1·0
% Mercury in purified sodium	0·01	0·01
Calcium used for purification per 100 kg. sodium, kg.	0·6	0·6
Hydrogen used m.^{3}/cell/day	0·7–1·5	0·5–1·0
Cell operating temperature	230–250° C.	230–250° C.
Temperature of purification of sodium	380° C.	380° C.
Cell voltage	1·5–1·9 volts	1·5–1·9 volts
Current efficiency	80–90%	80–90%
Length of sodium cell	900 mm.	2020 mm.
Width of sodium cell	700 mm.	1645 mm.
Height of sodium cell	980 mm.	1790 mm.
Nickel Anode Discs:		
Number	3	11
Diameter	600 mm.	1000 mm.
Thickness	5 mm.	15 mm.
Area	0·85 m.^{2}	10·6 m.^{2}
Current density	1660 amp./m.^{2}	1500 amp./m.^{2}
Revs. per minute	20–30	20–30
Drum diameter	50 mm.	300 mm.
Steel Cathodes:		
Number	4	12
Thickness	5 and 10 mm.	10 mm.
Active area	0·85 m.^{2}	9·5 m.^{2}
Current density	1660 amp./m.^{2}	1700 amp./m.^{2}
Anode to cathode, distance	15 mm.	15 mm.
Cast iron displacers, thickness	30 mm.	30 mm.
Displacers to discs, distance	5 mm.	5 mm.

gam in the cell rather than at the bottom. The electrolysis is carried out under a protective atmosphere of hydrogen.

Adequate amalgamation of the nickel discs is ensured by rotating them at 20–30 revolutions per minute in such a direction that the disc surfaces leave the amalgam at the point where the sodium concentration is highest. At higher speeds of rotation mercury loss tends to become excessive and the efficiency of sodium production diminishes. Nickel discs are superior to steel as the amalgam adheres more readily to nickel, and this permits the use of higher current densities. Current densities up to 3800 amp. per sq. m. can be used with monel and copper discs, but these materials corrode considerably more than nickel. The sodium in the amalgam dissolves in the melt and on electrolysis is deposited on the cathodes. The metal is molten at the temperature of operation and hence floats to the surface of the electrolyte where it is tapped off via the overflow pipe. On a small output the sodium tends to become viscous owing to the presence of sodium oxide and in these circumstances the metal may be removed by bailing.

During operation, hydrogen is bubbled through the melt from each hydrogen pipe. Reaction between the sodium hydroxide and sodium occurs to a small extent:-

$$NaOH + 2Na \rightarrow Na_2O + NaH.$$

The sodium hydride is said to be soluble in metallic sodium and to be thus removed from the cell. The sodium oxide forms a mud, however, which is reduced by the hydrogen. Sodium oxide may also be formed by ingress of air into the system. The reduction of sodium oxide by hydrogen is said to result in a slow build up of sodium hydroxide in the bath, so that sodium bromide and iodide must be added in the correct proportions every two days in order to keep the composition of the electrolyte constant. To keep the level of the bath constant it is of course necessary to remove some of the electrolyte from time to time. Sodium carbonate, which may be formed by contact of the melt with carbon dioxide from the air, appears to have a limited solubility in the electrolyte and may produce a sludge containing substantial amounts of carbonate. Originally nitrogen was used as the protective gas, but this was changed to hydrogen with beneficial results.[18]

The decomposition potential of the cell is given as 0·85 V. The cell voltage starts at 1·5 V. but rises to about 1·9 V. after about 120 days. This is accompanied by a drop in current efficiency from 95% to 85–90% and is taken as an indication that the cell has reached the end of its useful life. No trouble is experienced from carry over of sodium chloride with the amalgam, and the sodium chloride content of the electrolyte never exceeds 0·5%.[18]

The electrolyte freezes at about 220°C. and it is desirable to work as near to this temperature as possible in order to reduce contamination of the sodium with mercury. It is said that a further lowering of the melting point of sodium hydroxide through further additions of sodium halides is theoretically possible. This would offer the advantage of a smaller temperature difference between the chlorine and the sodium cells, and would also decrease the mercury content of the sodium, since this is attributed primarily to the vapour pressure of mercury.[16]

The use of an electrolyte of pure sodium hydroxide is unsatisfactory, because it is then necessary to work at temperatures above 300°C., and the considerable amount of mercury taken up by the melt disturbs the smooth operation of the electrolysis. Trouble is also experienced owing to fog formation in the electrolyte, which makes it difficult to deposit the liberated sodium in a coherent metal phase.[16]

The sodium bromide and iodide content of the electrolyte removed from the cells from time to time during operation, and at the end of the life of a cell, is recovered by recrystallization from aqueous solution. No figures are given, however, for the loss of sodium bromide and iodide occurring during cell operation.[18]

The sodium metal produced by the cell contains 0·5–1·0% of mercury, which renders the sodium hard and unusable, and also represents a serious loss of mercury. By passing the molten metal over calcium at 380°C., the mercury content of the sodium may be reduced to about 0·01%, but this is still appreciable and for some purposes may be deleterious. The calcium consumption is 0·6 to 1·0 kg. per 100 kg. of sodium. Mercury is recovered from the calcium by retorting, after which the calcium residue may be used for a further treatment. Mercury is also recovered by cooling the hydrogen which leaves the cell.[18]

It is said that the hazard from mercury poisoning in the process is no more serious than that when using ordinary mercury-type chlorine cells. Admittedly the operating temperature is considerably higher in the former case, but on the other hand the operations are carried out in an enclosed system.[18]

The following figures are given for the energy requirements of the amalgam route. The d.c. energy required for the recovery of the sodium by electrolysis of the amalgam is approximately 2·75 kWh. per kg. of sodium.[18] The total d.c. energy required, including the production of sodium amalgam by

Refs. p. 332

aqueous electrolysis, is estimated to be 9·85 kWh. per kg. of sodium.[2] Another estimate gives a figure of 10 kWh. for the d.c. energy required for the electrolytic production of 1 kg. of sodium by the amalgam route.[18] A comparison of the economics of the Downs cell and the sodium amalgam routes to sodium metal has been made on the basis of pilot plant data obtained at Gersthofen. This suggests that sodium from the amalgam route may be cheaper than that manufactured by the Downs Cell.[18,19] The design of a 16,000 amp. cell has been described, but apparently this cell has not actually operated.

Technical and economic aspects of the electrolysis of sodium amalgam as an anode using a molten electrolyte of sodium hydroxide, bromide or iodide have been reviewed.[19a]

The production of metallic sodium from sodium amalgam has been studied by Japanese workers.[20-23] The densities and electrical conductivities of fused sodium hydroxide, sodium bromide and sodium iodide systems have been determined.[21] The solubility of metallic sodium and other materials in molten mixtures of sodium hydroxide, sodium bromide and sodium iodide has also been determined.[22,23]

ELECTROLYSIS OF FUSED SODIUM HYDROXIDE

The most successful cell developed for the electrolysis of fused sodium hydroxide is the Castner cell.[1,2,3] Mellor has described the type of cell in operation when the original Treatise was written (Mellor,II,6) and an excellent account of the design and operation of a modern Castner cell, which was in service at Wallsend, England, till 1952, has been given by Wallace.[1]

The Wallsend Castner cell, shown diagrammatically in Fig. 2, is a cast iron pot set in brickwork. A cylindrical anode of pure nickel, made from fabricated plate, rests on a cast iron ring which in turn rests on the rim of the pot, and is insulated therefrom by asbestos board insertions. The cathode is of pure copper and consists of a cylindrical head carried by a stem. The bottom of the pot has an extended base pipe in which the cathode stem is centred and sealed in position by filling the pipe with molten electrolyte which is then allowed to solidify. The electrodes are located 1 in. apart and half way between them is an iron wire gauze diaphragm which permits free circulation of the electrolyte but prevents the globules of sodium reaching the anode. This diaphragm is suspended from a steel cylinder or inner pot resting in a recess in the top ring of the anode, from which it is insulated by asbestos, and extends downwards to the top of the anode: the attached diaphragm extends downwards to the full length of the cathode head. The inner

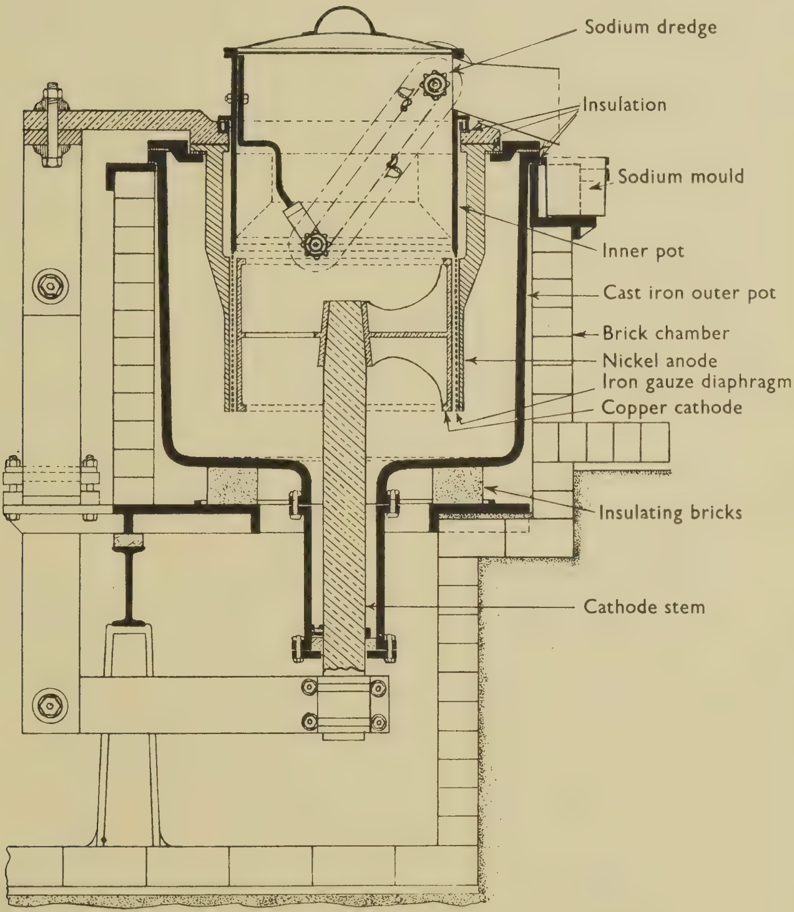

FIG. 2. CASTNER SODIUM CELL

cylinder is also fitted with a steel cover which fits closely enough to maintain an atmosphere of hydrogen in the pot, thus avoiding oxidation of the sodium collected there. The oxygen liberated at the anode leaves the cell by a vent from the space outside the cylinder. During electrolysis the sodium deposited on the cathode rises through the denser electrolyte and accumulates in the inner pot whence it is removed by means of a mechanically operated bucket elevator having iron wire gauze buckets. These buckets permit the electrolyte to drain from the mixture of sodium and electrolyte which they lift from the cell, but retain the molten metal. At the turn of its travel the bucket deposits the sodium in a small compartment whence the metal discharges into a mould. Make-up sodium hydroxide is fed into the anode compartment through an opening in the cell cover.

The cell, which has an internal diameter of 39 in. and measures 54 in. from the top to the bottom of the base pipe, holds about a ton of electrolyte. No external heating is applied to the cell, the current being sufficient to maintain the electrolyte in the molten condition.

The process yields sodium and hydrogen at the cathode and oxygen at the anode. It is not considered possible to collect the hydrogen, and although by the exercise of considerable ingenuity the oxygen has been recovered, this does not seem to be an economic proposition.

The cell bath consists of fused mercury cell sodium hydroxide with 10% of sodium chloride and 5–10% of sodium carbonate, and the working temperature is 300–310°C. It is essential to keep this temperature as near the melting point of the electrolyte as is practicable; otherwise the efficiency of sodium production falls off. The usage of sodium hydroxide is 2 pounds per pound of sodium or, allowing for sodium hydroxide recovered by aqueous leaching, 1·8–1·81 pounds per pound of sodium.

The sodium hydroxide fed to the cell contains small quantities of sulphate, calcium and silica, as may be seen from the analysis given in Table III (see page 337). These impurities tend to accumulate in the electrolyte as the bath grows older, and after about 70 days the efficiency falls off and it becomes necessary to shut down the cell. At this stage the electrolyte contains about 20% of sodium chloride, 15% of carbonate, 0·3% of silica, and 0·2–0·3% of sulphate, together with iron oxides in suspension. After the current has been shut off, the electrolyte is pumped out and allowed to solidify. The solidified electrolyte is then broken up and the caustic content recovered by aqueous leaching. The cell assembly is cleaned by washing with water.

It is interesting to note that aluminium makes a very good cathode and is not appreciably attacked by molten sodium or sodium hydroxide. It cannot be used in practice, however, as it will not resist the strong hot aqueous sodium hydroxide solution formed when the cell is being cleaned after dismantling, as described later. On the other hand it was found that aluminium is of no use as an anode: the current passes momentarily and then falls to zero, presumably owing to the formation of a film of oxide on the metal.

The cells are operated in series with a current of 8500–9500 amp. giving a cathode current density of approximately 7 amp. per sq. in. The yield of sodium is 0·4 g. per amp. hr. and 90 g. per kWh.[1] If the decomposition potential of sodium hydroxide is taken as 2·25 V. at the temperature of cell operation, and the cell current efficiency is 40%, then the energy efficiency can be calculated to be 18%.[4–6]

Little seems to have been published regarding Castner cell installations that are now operating, or have at one time operated, in countries other than the United Kingdom. However, a brief account of the development and operation of a Castner cell by the Niagara Electrochemical Company at Niagara Falls, N.J. has been given.[2] The cell appears to have been very similar to the Wallsend cell, operating at 7000 amp. and 4·3 V. This plant was shut down in 1925. A modified Castner cell has operated in Norway.[2a]

Little information is available regarding the Castner cell plant operated by the I.G. Farbenindustrie at Gersthofen, Germany. The electrolyte is described as caustic soda and the cell is said to operate at 330°C. at 4·5 V. at about 36% current efficiency, with an overall energy consumption of 21 kWh. per kg. of sodium, starting from sodium chloride.[7]

Mechanism of Electrolysis of Sodium Hydroxide.

The mechanism of the electrolysis of fused sodium hydroxide is discussed at length in the original Treatise (Mellor,II,6), and may be briefly summarized by saying that half the current is used to electrolyze water and that under normal running conditions the maximum possible efficiency of sodium production is 50%. Attempts made to exceed this efficiency by removing water from the anode compartment by means of a current of dry air,[8] or by structural changes to the anode and diaphragm[9] seem to have been unsuccessful in practice.[1] According to a recent patent, the loss of metal which takes place owing to reaction with water and oxygen at the cathode may be minimized by continually passing a portion of the fused electrolyte into a separate zone where it is heated to a temperature of 410°C., above that of the electrolysis zone (300-310°C.) in a countercurrent of dry air, thus vaporizing dissolved water from the electrolyte.[9a] It has been stated that the complete removal of the water from the electrolyte does not improve the yield of sodium, since the water is necessary to prevent pyrosol formation at the cathode, and laboratory experiments have shown that, when diffusion of the anodic water towards the cathode is completely suppressed by the addition of sodium to the anolyte or by interposing a zirconia diaphragm between the electrodes, current efficiencies approaching 100% are not obtained; on the contrary, the catholyte assumes a dark brown appearance and formation of hydrogen and sodium comes to a complete stop, the current efficiency falling to zero.[10] Wallace describes a similar phenomenon occasionally encountered in the operation of the Castner cell on the technical scale.[1] In this connexion it should be noted that the essential claim in Castner's original patent is that the temperature of electrolysis should be kept as near as possible to the melting point of the electrolyte, and in any case must not exceed it by 20°C.[1] If the removal of sodium from the cell is neglected and large amounts of metal are allowed to accumulate in the cell and the electrolyte is allowed to become too hot, a stage is reached when so much sodium has dissolved in the sodium hydroxide that the electrolyte starts to function as a metallic conductor and the current passes without producing any electrolysis. It is interesting to note that such a cell, which is described as being 'dead', can be revivified by the drastic but effective procedure of adding water to the electrolyte in the outer pot. The water dissolves in the electrolyte and reacts with the metallic sodium in solution to give sodium hydroxide, and electrolysis restarts. There seems, however, to be some doubt as to what happens when sodium dissolves in molten sodium hydroxide. According to von Hevesy, sodium dissolves in sodium hydroxide to form a true solution and the solubility decreases with increasing temperature. The rapid fall in current efficiency which takes place at tempertures above about 330°C. when electrolyzing fused sodium hydroxide is therefore not a result of the increased solubility of sodium in the electrolyte but is caused by the increased rate of diffusion of the metal in the electrolyte at higher temperatures (Mellor,II,448). Hevesy states that the metallic sodium can be deposited from its solution in sodium hydroxide by increasing the temperature[11] and a recent patent proposes to recover sodium from solution in sodium hydroxide in this way.[12] Other workers[13-13b] state that a reaction may take place between the sodium hydroxide and the sodium to form sodium monoxide and hydrogen if the temperature is sufficiently high, according to the equation: $NaOH + Na \rightarrow Na_2O + \frac{1}{2}H_2$. This reaction begins at 450°C. and proceeds vigorously at 550°C., but at the operating temperature of the Castner cell is likely to be extremely slow. Later workers,[14,15] studying the reaction of sodium with molten sodium hydroxide at temperatures corresponding approximately to Castner cell operating temperatures, find by *X*-ray studies that the sodium reacts with the hydroxide to form sodium monoxide and sodium hydride according to the equation:-

$$2Na + NaOH \rightarrow Na_2O + NaH.$$

Under these conditions the monoxide and the hydride remain in solution in the melt, and very little hydrogen is evolved.[16,17] A recent patent proposes the addition of sodium bromide or iodide, or a mixture of these two salts, to fused sodium hydroxide electrolyte, in the range of from 15 to 42 mol.-% in order to decrease the solubility of water in the electrolyte and so increase the current efficiency of electrolysis.[18] According to another patent, the secondary reaction that takes place on the electrolysis of fused sodium hydroxide, whereby the liberated hydroxyl ions combine to form water and oxygen, causing a marked decrease in current efficiency of sodium production, can be suppressed by carrying out the electrolysis in the presence of an auxiliary sodium salt, such a salt being able through a secondary chemical reaction to combine with the hydroxyl ion to reform the compound undergoing electrolysis with simultaneous production of gaseous products, such as ammonia, inert towards the molten electrolyte.[19,20] A suitable auxiliary salt is sodamide. Thus when fused sodium hydroxide is electrolyzed in the presence of fused sodamide the following reactions occur:-

1. $NaOH + (+)(-) \rightarrow Na^+ + OH^-$
2. $2OH \rightarrow H_2O + \frac{1}{2}O_2$
3. $H_2O + NaNH_2 \rightarrow NaOH + NH_3$.

The use of sodamide in the electrolysis of sodium hydroxide is advantageous in that the melting point of the bath is lowered, and the secondary reaction between sodium and water, which results in hydrogen formation, is suppressed. Moreover when sodamide is present the volume of gas evolution at the cathode is twice that obtained in the electrolysis of sodium hydroxide alone, and this favours the elimination as water vapour of part of the water produced by the electrolysis, so reducing the quantity of sodamide required for the fixation of water. It is claimed that the suppression of water formation at the anode more than doubles the current efficiency of sodium production.

It is stated that the efficiency of production of sodium by the electrolysis of sodium hydroxide tends to fall off as electrolysis proceeds owing to polarization. It has been proposed to overcome this effect by washing the cathode in water from time to time[21] or by periodic changes of polarity, the cathode becoming the anode for about 2 min. after the cell has been running for 8 to 12 hr.[21] It has also been proposed that when the electrolysis is carried out using a copper or copper alloy cathode and a slightly oxidized anode such as iron or nickel alloy, the cathode should be treated at intervals during the process to form a thin film of oxide and it is suggested that this may be done by reversing the current for a period of 2 to 10 seconds.[22,23] The effect of polarization in a Castner type cell has been studied on the semi-industrial scale by Pinck and Ledig, who found that the yield of sodium was increased by periodic inversions of the current for short periods.[21]

Influence of Impurities on the Electrolysis of Fused Sodium Hydroxide.

Wallace has discussed the effect of impurities in the electrolyte on the electrolysis of sodium hydroxide in the Castner cell.[1]

The purity of the sodium hydroxide used in the process is most important, and for satisfactory operation it is essential to use anhydrous sodium hydroxide made by a mercury brine cell process. Diaphragm cell sodium hydroxide is not recommended. For purposes of comparison typical analyses of diaphragm and mercury cell sodium hydroxide liquors are given below. It will be seen that the difference between the two materials is small, but nevertheless it appears to be sufficient to have a profound effect on cell operation.

The electrolysis of fused sodium hydroxide is especially sensitive to the presence of traces of sulphate, calcium or silica. According to Wallace,[1] when silica is present in the electrolyte, silicon is deposited at the cathode as the electrolysis proceeds, and this interferes with the operation of the cell. It is, however, uncertain how much sulphate can be tolerated, and cells have operated well with as much as 0·4% of sulphate in the bath. Similarly it is not known how much calcium can be tolerated in the electrolyte: cells have run well with as much as 0·046% of calcium carbonate in the electrolyte, but the addition of small quantities of calcium chloride rapidly reduces the yield of sodium and the electrolysis has been rendered completely unworkable by the use of sodium hydroxide to which 1 lb. of calcium oxide per ton of hydroxide was added during manufacture.[1] On the other hand the presence of sodium chloride and sodium carbonate in the electrolyte is beneficial and it is customary to work with a bath containing these materials.

TABLE III.- TYPICAL ANALYSES OF SODIUM HYDROXIDE[24,25]

Constituent	Concentration in Weight %		
	Diaphragm Cell Unpurified	Diaphragm Cell Purified	Mercury Cell

ELECTROLYSIS OF FUSED SODIUM CHLORIDE

When Mellor wrote the original Treatise, the supremacy of the Castner cell as a means of manufacturing sodium was unchallenged, and although many attempts had been made to obtain the metal by electrolysis of fused sodium chloride, the efforts of the inventors had met with no permanent success. Since then, however, the position has been completely altered by the development of the Downs cell, and in these changed circumstances it may therefore be appropriate to give a brief account of the various steps that have led to the successful manufacture of sodium by electrolysis of fused sodium chloride. For more detailed information reference should be made to the numerous published accounts of the development of fused salt cell design and operation.[1-3,26-29]

The manufacture of metallic sodium by electrolysis of sodium hydroxide in the Castner cell suffers from at least two serious drawbacks. The maximum theoretical current efficiency which can be obtained from the cell, as operated under practical running conditions, is 50%, and the raw material used in the electrolysis is anhydrous sodium hydroxide, which for successful operation must have been made by the mercury brine cell route and is comparatively expensive.[1]

The principal and indeed almost the sole source of sodium in nature is common salt, and as a raw material this has a number of advantages over sodium hydroxide. Salt is considerably cheaper than the hydroxide, and is also more readily obtained in a pure condition. Moreover the electrolysis of sodium chloride yields not only sodium but also chlorine as a valuable by-product, and it is also possible to operate at higher current efficiencies than are attainable using sodium hydroxide.

There are, however, a number of very serious disadvantages attending the use of fused sodium chloride. Pure sodium chloride melts at about 804°C., and a considerably higher cell temperature must therefore be maintained during the electrolysis than is required in the Castner cell which operates about 310-320°C. Sodium boils at 880°C. and has a very substantial vapour pressure at 850°C., which is likely to be the approximate working temperature of a cell operating with an electrolyte of pure fused sodium chloride. Even at 600°C., which is about the operating temperature of some cells using low melting-point electrolyte baths, sodium burns very readily in air, and this complicates the design of the cell considerably. These high operating temperatures also create serious corrosion problems, and trouble is experienced from anode effect[30] and metal fog formation *i.e.* solution or dispersion of the sodium in the fused electrolyte.[26] Thus it is understandable that for many years processes intended for the manufacture of sodium by the direct electrolysis of fused sodium chloride proved to be unworkable when tried out on the industrial scale.

Attempts were made to overcome these difficulties in two different ways:-

1. The use of a molten metal cathode in which the liberated sodium dissolves to form an alloy, from which sodium may be recovered by subsequent treatment.
2. The addition of other salts to the fused bath in order to get a low-melting electrolyte.

As might be expected, the above methods of working, while eliminating some of the disadvantages attached to the direct electrolysis of pure fused sodium chloride, introduce in their turn other difficulties which in some cases have been found to outweigh the advantage gained.

From about 1890 to about 1909 most work seems to have been directed towards the development of cells employing a molten metal cathode. The first successful cell of this type was the Acker cell[31] where fused sodium chloride was electrolyzed in the presence of a molten lead cathode to give a sodium-lead alloy which was then denuded by steam in a separate compartment to give anhydrous sodium hydroxide. The cell suffers from the drawback that it does not in fact manufacture metallic sodium except in the form of a sodium-lead alloy, from which the sodium is recovered not as the metal but as the hydroxide. This type of cell may be considered the high temperature analogue of the Castner cell for the electrolysis of brine, molten lead replacing the mercury, and the recovery of anhydrous sodium hydroxide by treatment of the sodium–lead alloy with steam corresponding to the denuding of the amalgam with water.

An Acker cell plant with a maximum output of about 6 tons of sodium per day ran for several years at Niagara in the United States, but was eventually completely destroyed by fire in the year 1907 and was never restarted.[26]

The Ashcroft cell,[32] which was at one time subjected to full-scale tests in Norway, consisted of two compartments. In the decomposing compartment fused sodium chloride was electrolyzed and the liberated sodium dissolved in a molten lead cathode. This alloy was then circulated to a producing compartment where it served as anode in a bath of molten sodium hydroxide. On electrolysis the sodium passed into the electrolyte and was re-deposited on a nickel cathode submerged in the melt. A hood immediately above this cathode collected the globules of sodium which rose in the melt from the cathode, and this sodium then overflowed through a pipe into a receiver. The cell therefore produced metallic sodium and not merely a sodium–lead alloy. Ashcroft used a crude salt, and this gave rise to deposition of impurities on the molten cathode which led to increased voltage troubles. The process did not become established commercially.

The molten metal cathode routes to sodium failed to obtain lasting success on the commercial scale and may be considered, in the words of Hardie,[26] to represent a false start to the solution of the problem of the electrolysis of fused sodium chloride.

However, an interesting recent industrial development, whereby a fused sodium chloride–potassium chloride mixture is electrolyzed in the presence of a molten lead cathode in order to produce a sodium–lead alloy, suggests that in some circumstances this route may offer advantages over the now well established electrolysis of sodium chloride–calcium chloride electrolytes.[7]

Following the failure of the molten metal cathode routes to establish themselves, attention was once again directed toward the direct electrolysis of fused sodium chloride, either in the pure state or in electrolyte mixtures of lower melting point.

In 1924 Danneel described work carried out prior to the 1914–1918 war on the large scale production of sodium by the electrolysis of sodium chloride.[27,28,33] The electrolysis was carried out in a bath consisting of 72% of sodium chloride, 10% of potassium fluoride and 18% of sodium fluoride, melting at 610°C. Sodium so made always contains a small amount of potassium, but very little fluorine is produced at the anode. It is said that the formation of fluorine is undesirable as it reacts with the graphite of the anode to give carbon tetrafluoride. Other bath compositions were tried. A mixture of 70% of sodium chloride and 30% of potassium fluoride melts at 550°C. but on electrolysis gives a product containing about 2% of potassium: there is, however, no fluorine in the chlorine simultaneously liberated. An electrolyte containing 6·5% of potassium and 11·7% of fluorine gives a metal resembling pure sodium but containing 0·5–0·6% of potassium, and the chlorine liberated contains appreciable amounts of fluorine.

More recently other fluoride-containing electrolyte baths have been proposed for the electrolysis of sodium chloride.[34] Thus sodium has been made by the electrolysis of a mixture of 62·5% of sodium chloride, 12·5% of potassium chloride and 25% of sodium fluoride. The electrolysis is carried out in a talcochlorite-lined cell at 620–650°C., and is said to proceed normally even at anode current densities as high as 0·3 to 0·5 amp. per sq. cm.

About 1909 the so called 'Ciba' cell was developed in Switzerland by the Gesellschaft für chemische Industrie in Basel.[35,36] The electrolyte was fused sodium chloride, or mixtures thereof with other salts, and the sodium and chlorine produced by the electrolysis were separated by means of a diaphragm or diaphragms. The cell carried an arrangement of heating resistances and additional electrodes for melting the electrolyte by means of alternating current. The cell operates at about 6000 amp. and 10–11 V. with an energy consumption of about 2500 kWh. per 100 kg. of sodium.[36] The Ciba cell is shown diagrammatically in Fig. 3. It may be regarded as a modified Castner cell adapted to the electrolysis of fused sodium chloride. In 1926 the output of Ciba cell sodium was about 500 tons per year, so that the cell must be considered to have attained a fair degree of technical success.[35] No recent production figures are available.

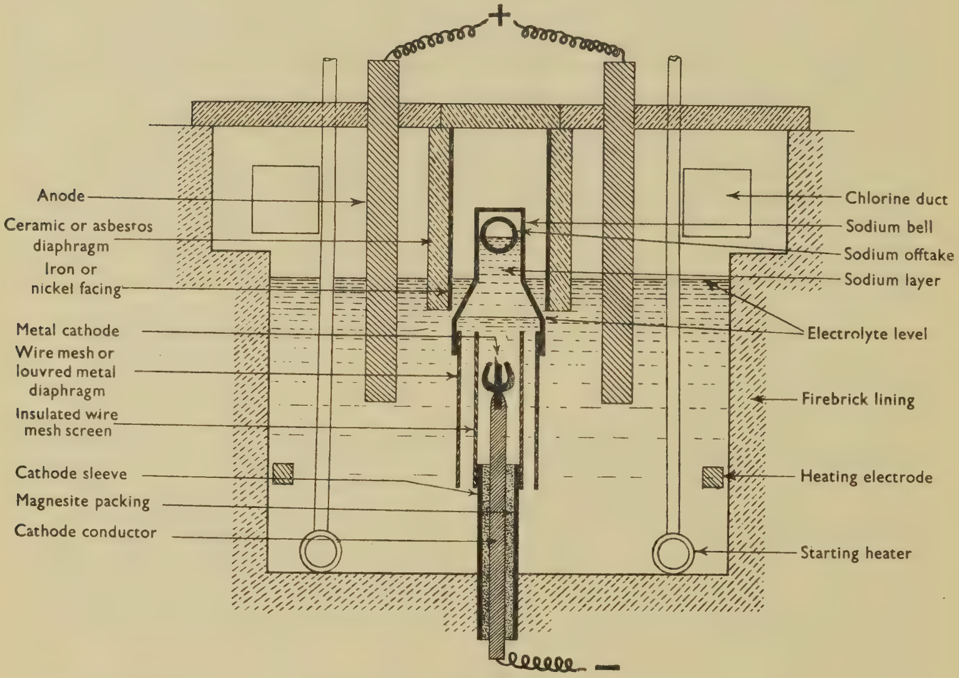

FIG. 3. CIBA SODIUM CELL

The McNitt cell, shown in Fig. 4, was patented in 1917: it appears to represent a considerable advance and may be considered the forerunner of the Downs cell.[37] In this cell the collecting chamber is submerged in the electrolyte to such a depth that the liberated sodium, which is considerably less dense than the electrolyte, automatically rises up a pipe to a level at which it overflows into a receiving vessel. The cathode is located centrally inside the anodes, and the cell is fitted with a diaphragm which serves to separate the sodium deposited at the cathode from the chlorine liberated at the anode. Later patents by McNitt propose a number of modifications in cell design which would appear to be equally applicable to other fused halide cells such as the Downs cell.[38-43a]

The Downs cell, patented in 1924,[44] succeeded in solving the problem of making sodium by the electrolysis of fused sodium chloride, and has been extensively adopted on the commercial scale, not only in the United States where it originated, but also in a number of other countries including England and Germany. The basic Downs cell is shown diagrammatically in Fig. 5. A number of modifications to the cell have been described in patents.[41-43,45-47]

The Downs cell, like that of McNitt, makes use of a hydrostatic head of

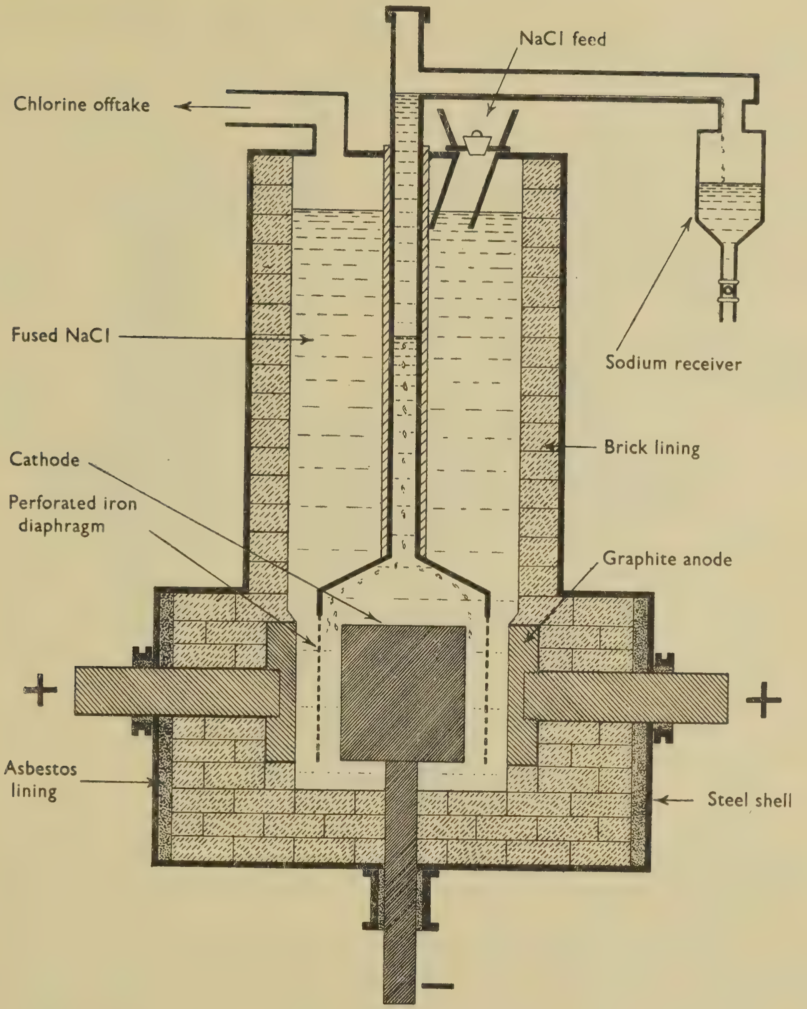

FIG. 4. McNITT SODIUM CELL

electrolyte to ensure that the sodium produced may be removed from the cell continuously and automatically, but it is distinguished from the Castner cell, the McNitt cell and many others devised for the electrolysis of sodium chloride by the novel feature that the anode is located inside the cathode. A considerable amount of information has been published regarding the modified type of Downs cell operated at Knapsack near Cologne in Germany by the Deutsche Gold- und Silberscheideanstalt vormals Roessler, commonly referred to as 'Degussa', and many details of design, construction and operation are given.[36,48,49] American cells have also been described, but in considerably less detail.[29] The design of the American cells differs somewhat from that of the German cell. The Knapsack cell is illustrated in Fig. 6 and is briefly described below. For further details the reader should consult the original publications on the subject. A Downs cell installation in England has also been described.[49a,b]

The body of the cell is a steel shell lined with refractory brick. A com-

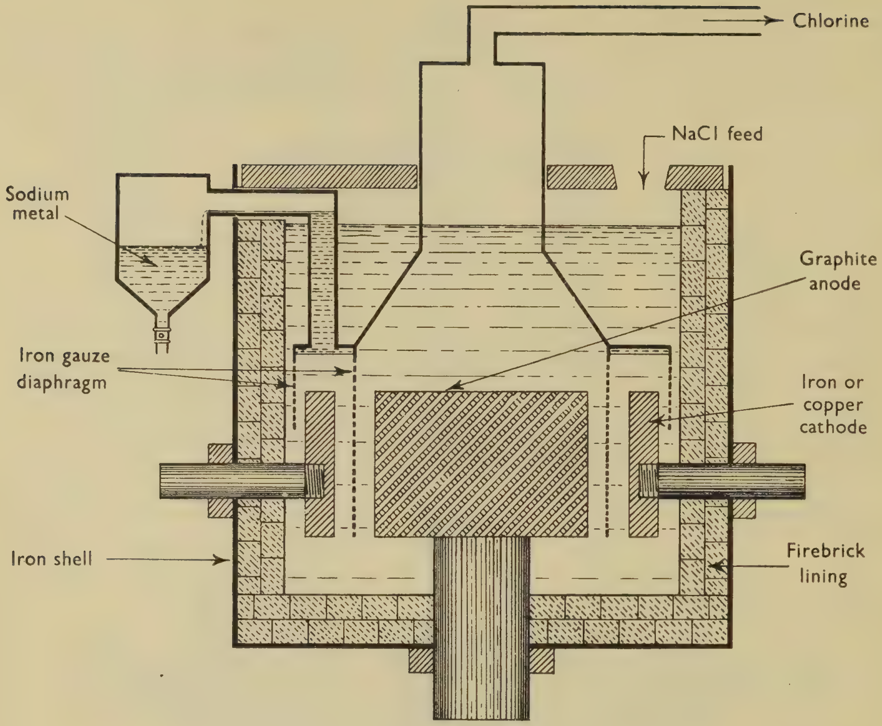

FIG. 5. DOWNS SODIUM CELL
AFTER U.S. PATENT NO. 1,501,756

posite cylindrical graphite anode assembly consisting of a number of accurately machined pieces of graphite, bolted together to give a square cross section at the bottom, projects upward through the cell bottom and is located centrally in the cell where it is surrounded by the cathode. In the case of the 24,000 amp. cell this assembly is made up of 8 graphite pieces, whereas in the 32,000 amp. cell only 4 pieces are used. The cathode is a cylindrical ring of cast steel, supported by two arms extending through the sides of the cell body to the electrical connexions. A conical brick-lined bell or dome, submerged in the electrolyte and situated directly above the anode, serves to collect the chlorine. A diaphragm suspended from the dome into the electrolyte prevents the sodium coming in contact with the chlorine. The diaphragm is made of 16 mesh steel gauze and is fitted with stiffening bands to help it to retain its shape at the temperature of the cell. Somewhat surprisingly this steel gauze does not appear to be appreciably attacked by the hot dry chlorine produced during the electrolysis. The dome also carries an inverted trough, located over the cathode, which collects the sodium. This sodium collector is submerged in the electrolyte so that the sodium produced by the electrolysis rises upward, by virtue of the difference in density between molten sodium and the electrolyte, through a riser pipe, and overflows into an external receiver. This riser pipe is cooled by radiation and this reduces the temperature of the sodium flowing through it.

The electrolyte bath is a mixture of about 42–41% of sodium chloride and 58–59% of calcium chloride the low melting-point of which enables the cell to operate at about 590 ± 5°C.[48] A number of patents describe devices for ensuring that an adequate circulation of electrolyte in the electrode gap is

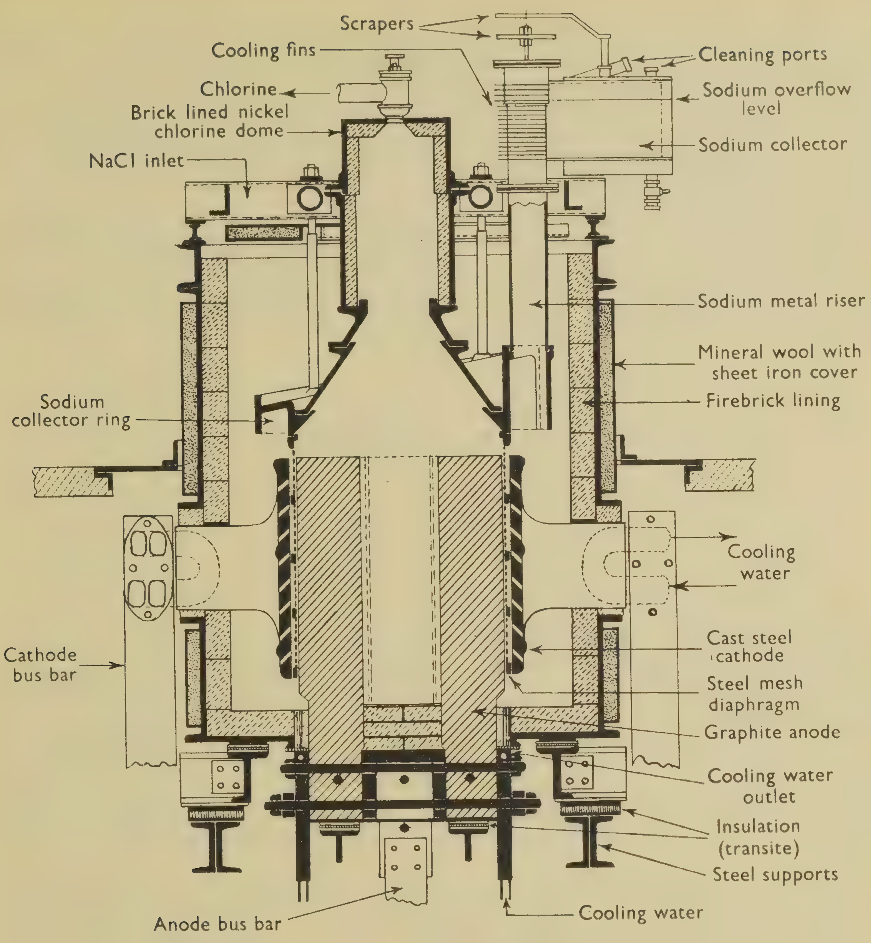

FIG. 6. KNAPSACK 24,000 AMP. SODIUM CELL

maintained.[38,40,47-47b] Dry sodium chloride is fed continuously to the cell during electrolysis.[48] The sodium initially produced by the cell contains a few per cent. of dissolved calcium metal which, owing to the limited solubility of calcium in sodium at lower temperatures, is deposited as the sodium ascends the riser or cooling pipe. Owing to its comparatively high density as compared with liquid sodium, the calcium deposited sinks back into the electrolyte where it reacts to form the equilibrium alloy.[48,51-53] The purification of the sodium is described later (see page 344).

The cell is insulated from the ground to prevent current leakage, and the mobile sodium-collecting receiver has rubber tyres for insulation. The chlorine produced by the cell is removed under slight suction.

The Knapsack plant consisted of 65 Downs cells operated in two banks, one of about 40 and the other of 25 cells. In 1946 the standard cell at Knapsack was of 24,000 amp. capacity but experimental cells of 27,000 amp. and 32,000 amp. were also in existence. Operating details of the cell are summarized in Table IV (see page 345). It has been stated that in 1954 Downs cells generally operate at 28,000–35,000 amp., the trend in recent years being towards an even higher capacity.[26]

The amount of calcium carried out of the cell into the sodium receiver has been much reduced by providing external cooling fins on the cell riser pipe, so that the sodium-calcium alloy, produced in the cell at temperatures around 600°C., is cooled to about 100–200°C.[52] As the alloy ascends the pipe the temperature falls, till a stage is reached where the concentration of calcium exceeds its solubility in sodium, when it is precipitated and falls back into the cell. An automatic device for removal of deposits from the sodium riser pipe has been patented.[52a,b]

The separation of electrolyte and sedimentary impurities from the sodium before it leaves the cell has been the subject of a number of patents.[55-60]

According to one source, the calcium content of the sodium leaving the cell is about 0·5–1·0%.[26] On the other hand, a patent gives the following figures for the calcium content of sodium leaving a cell.[61]

Temperature of liquid sodium leaving the cell °C.	% Calcium in the sodium leaving the cell
210	0·21
170	0·20
160	0·20
135	0·15

This sodium is then further purified by cooling it to about 110°C., at which temperature the solubility of calcium in sodium is very low, and filtering it (see also page 352). After filtration the sodium contains about 0·04% of calcium.[48,54,62,63] According to a patent, further purification from calcium may be effected by subjecting the molten sodium to the action of an oxidizing agent, such as air, at a temperature not lower than 350°C., to convert the calcium to calcium oxide[64] which is then separated from the sodium by filtration after cooling to a temperature just above the melting point[64] (see page 358).

In another patent it is proposed that the sodium-calcium alloy from the cells should be freed from calcium by passing it over solid sodium chloride at 500–700°C. when the calcium reacts with the sodium chloride to form calcium chloride and metallic sodium.[65,66]

The residues accumulating on the filter, generally known as Downs cell sludge, are removed from time to time and treated in a hydraulic press which serves to remove most of the sodium. The final residue from the press is then returned to an old cell approaching the end of its useful life where sodium is recovered according to the equation:[48,68-74] $Ca + 2NaCl \rightarrow CaCl_2 + 2Na$. Other methods of treating cell sludge are discussed later (see page 352).

The Knapsack cells are operated in the following manner.[48] Before a new cell is started up, the brickwork is thoroughly dried out for a week by a low charcoal fire burned in the space between the anode and the brickwork. The cell is then started up without the sodium collector ring, diaphragm etc. being in place. Four graphite wedges are placed 90° apart between the anode and the cathode and the cell is filled with broken lumps of solidified electrolyte. Full current is then passed through the cell, and the heat developed is sufficient to melt the electrolyte. During this operation a hood is placed over the cell and connected to the vent suction line in order to remove the unpleasant fumes formed. When the cell is full of molten electrolyte at about 600°C. the graphite wedges are withdrawn, the hood is removed, and the chlorine and sodium collecting assembly, together with the diaphragm, installed. The chlorine produced directly after a cell starts up tends to be of low concentration for several days and is consequently removed via the dilute

TABLE IV. - OPERATING DATA FOR KNAPSACK DOWNS CELL

	24,000 amp. Cell	32,000 amp. Cell
Production		
Sodium metal per day	385 kg.	515 kg.

gas main. When the cell is operating normally the gas produced contains about 92–96% of chlorine, the rest being air and small quantities of carbon oxides from oxidation of the anode.

A new cell starts up with a voltage of 5·7 V., but as the anodes wear this gradually increases to about 6 V. When the cell is first started up, all the thermal insulation is in place, and the temperature of the electrolyte is about 585°C. This cell temperature is measured twice a week during the life of the cell, and, as the voltage increases owing to anode wear, the temperature rises owing to the increased resistance of the electrolyte and the cell insulation, which is in two halves, one above and one below the operating floor, is removed, the bottom section being taken away first. Finally, in spite of the removal of the insulation, it is found that the electrolyte temperature rises to 595°C. at 6 V.; the cell is then considered to have reached the end of its useful life and is accordingly shut down.

The cell life is given as 300–350 days, and it takes two or three days to dismantle an old cell and instal a new one. During cell operation it is found that the voltage may rise suddenly to 8·5–9 V., and this is rectified by changing the diaphragm. Failure of the diaphragm has not been satisfactorily attributed to a single cause and it is suggested that it results from a number of chemical and thermal effects. According to a patent, the need for a diaphragm in the production of sodium by the electrolysis of fused chloride may be eliminated by the use of a porous carbon electrode with a centre cavity and gas conduit for removal of the chlorine during electrolysis.[48a]

A diaphragm lasts about 20 to 30 days, and the cell is out of production for about 4 hours while the change is being made. During this period the assembly which carries the diaphragm is removed from the cell and the electrolyte is filtered through a conical 16 mesh steel gauze filter. This filter is suspended above the cell and the electrolyte pumped from the bottom of the cell into the filter by means of an airlift using dry air. This airlift arrangement is also used to empty a cell which has reached the end of its useful life, when the electrolyte is discharged into iron vessels and after solidification is used as charging material for starting up a new cell. Operational conditions vary. Thus, in the United States the cell is described as operating at about 7 V. with a current efficiency of about 80–85%.[29] This corresponds to an energy consumption of 5 kWh. of a.c. power per pound of sodium, after allowing for a 6–8% loss in converting from a.c. to d.c. power.[29]

Determination of the back e.m.f. and calculations based on thermodynamical data indicate that the decomposition voltage of the cell is about 3·45 V. and the difference between this figure and the actual cell voltage is therefore required to overcome the resistance of the electrolyte, and electrode connexions etc.[26]

Hardie gives the following comparison of the energy efficiency of the Castner and the Downs cell.[26] Assuming a current efficiency of 80% and a working voltage of 7, the energy efficiency of the Downs cell is approximately 39%. If the figure 6 is taken as the voltage for the Knapsack cell, the energy efficiency becomes about 46%. With the Castner cell the highest efficiency obtained is about 24%, and as the sodium hydroxide used in the cell is produced from salt electrolyzed in a brine cell at an efficiency of about 60%, the overall efficiency is at best only slightly over 14%. The energy efficiency of the Downs process is therefore about three times that of the two stage Castner process from salt to sodium. This being so, it is scarcely surprising that the Castner process, after many years of unchallenged supremacy in production of electrolytic sodium, is now almost completely superseded by the Downs cell, and may be expected to become obsolete before long.

Purity of Downs Cell Sodium.

The sodium produced by the Downs cell attains a degree of purity seldom found in a commercial material. The sodium content of the metal is 99·95%,[75] and the following are present as impurities:-[75]

	%
Silicon	0·007
Iron	0·002
Calcium	0·012
Boron	0·05
Chlorine	0·0067
Nickel	0·0004
Aluminium	0·0001
Phosphorus	0·005
Sulphur	0·009
Heavy metals	0·028
Hydrogen[76]	0·006

Small amounts of sodium oxide and hydroxide are also present. Degussa also produce a special quality of sodium which contains less than 0·001% of calcium. This is made from the ordinary Downs cell sodium by a purification process.[36]

Downs Cell Chlorine.

The Downs cell produces chlorine in addition to sodium. For a discussion of the handling and purification of chlorine produced by electrolysis the reader is referred to Volume II, Supplement 1.

The Downs Cell Electrolyte.

The composition of the electrolyte bath used in the Downs cells operated in the United States differs from that adopted in Germany. Thus, in the United States the cells work at approximately 600° C. with an electrolyte consisting of a eutectic of 66·8% of calcium chloride and 33·2% of sodium chloride[29] whereas German practice favours an electrolyte containing 58–59% of calcium chloride and 41–42% of sodium chloride with an operating temperature of 585–595° C.[48]

The sodium chloride used in the cell must be anhydrous and free from sulphate.[48] In Germany this feed salt is purified by dissolving rock salt in water and treating the solution with barium carbonate and caustic soda. The treated brine is then filtered and evaporated in triple effect evaporators, after which the salt is removed as a slurry, centrifuged and dried at 300–400°C. before being stored. About 105–110 kg. of crude salt and 0·091 kg. of barium carbonate are required to produce 100 kg. of refined salt. No figure is given for caustic soda consumption.[48]

A method has been patented for the purification of a halide such as sodium chloride, for use in an electrolytic cell, by heating it and fusing it in a compartment of the cell, separated from that in which electrolysis takes place, in order to remove moisture and impurities capable of being volatilized under these conditions.[77]

A make-up of calcium chloride equivalent to about 4 kg. per 100 kg. of sodium produced must be added to the electrolyte to replace the calcium removed in solution in the sodium.[48]

The fundamental reaction taking place on electrolysis of fused sodium chloride is very simple and may be represented thus:-

$$\underset{\text{(liquid)}}{2\mathrm{NaCl}} \rightarrow \underset{\text{(liquid)}}{2\mathrm{Na}} + \underset{\text{(gas)}}{\mathrm{Cl_2}}$$

In the Downs cell, however, matters are more complicated owing to the presence of calcium chloride in the electrolyte, and the equilibrium $CaCl_2 + 2Na \rightleftharpoons 2NaCl + Ca$ must also be considered. The first quantitative study of this equilibrium appears to have been made by Jellinek and Czerwinski.[78] These workers did not use pure calcium and sodium, however, but alloys with a large excess of lead, and it is therefore needless to consider these results further. Lorenz and Winzer examined the equilibrium at temperatures varying between 600°C. and 800°C., and give the following figures for the equilibrium at 500° and 600°C. (Table V).[79,83]

TABLE V. - EQUILIBRIA IN THE REACTION:
$CaCl_2 + 2Na \rightleftharpoons 2NaCl + Ca$

Molecular %		Atomic %	
Sodium chloride	Calcium chloride	Sodium	Calcium
Equilibrium at 500°C.			
48·1	51·9	99·49	0·51
48·4	51·6	99·12	0·88
49·4	50·6	99·06	0·94
48·0	52·0	99·13	0·87
Equilibrium at 600°C.			
47·3	52·7	98·80	1·20
46·5	53·5	99·09	0·91
55·8	44·2	99·51	0·49
56·8	43·2	99·22	0·78

According to these results the equilibrium concentration of calcium in sodium at Downs cell working temperatures is not likely to exceed about 1 mole per cent. Lorenz and Winzer also claim, however, that over a considerable range variation in the composition of the salt phase is not accompanied by any change in the total composition of the metal phase. The equilibrium has more recently been investigated in much greater detail by Rinck[80] who points out that Lorenz and Winzer's results do not obey the Phase Rule. Rinck considers that the conditions under which these authors carried out their experiments were likely to produce inaccurate results. He points out that the starting materials were sodium and calcium chloride, and that it is difficult to obtain calcium chloride in the pure state. Moreover, Lorenz and Winzer worked in Jena glass which, while it has an appreciable mechanical resistance at 800°C., is nevertheless heavily attacked by the equilibrium mixture, and because of the absorption of air by the calcium the glass tubes were flattened by external pressure which rendered good separation of the phases impossible. Rinck on the other hand worked with pure calcium and pure sodium chloride as starting materials, and in steel tubes which readily withstood the highest temperatures and were not attacked by the equilibrium mixture. Unfortunately Rinck studied the equilibrium only at 712°C. and higher temperatures, and no results are available for Downs cell working temperatures, but he gives the following values for the solubility of calcium in sodium:-

Temp. °C.	Atomic % calcium
1100	16·5
975	10·85
850	7·26
712	4·0

By extrapolation from these data a value of about 4·0 weight-% may be inferred for the solubility of calcium in sodium at 600°C., which may be regarded as approximately the cell working temperature. According to another source the solubility of calcium in sodium at 600°C. is about 5·5 weight-%.[29]

Thus, the metal phase in the Downs cell is not pure sodium but an alloy of sodium and calcium, the composition of which will depend on the respective concentrations of sodium chloride and calcium chloride in the electrolyte, and on the cell temperature.

The amount of calcium in the Downs cell sodium is not known, but calculations based on the calcium–sodium equilibrium diagram and thermodynamical data indicate a concentration of 3–4 weight-% at the eutectic composition,[26] 66·8% of calcium chloride, as used in America.[29] With the German electrolyte containing 58% of calcium chloride the calcium content of the sodium may differ from that in the American cells. In neither case, however, can the equilibrium concentration of calcium exceed the solubility of calcium in sodium, since otherwise deposition of calcium would occur in the cell.

The solubility of calcium in sodium has been given as 1·38 weight-% at 700°C.,[79] 6·76 weight-% at 700°C.[80] and more recently as 5·5 weight-% at 600°C., falling rapidly to about 4 weight-% at 400°C. and 0·01 weight-% at the melting point of sodium, 97·5°C.[29]

The so called fog formation resulting from the solubility in the electrolyte of the metal produced by the electrolysis is of great importance in practice, since it leads to current inefficiency, as sodium chloride is reformed from the sodium in solution by reaction with the liberated chlorine at the anode. Workers who have attempted to prepare sodium by fused salt electrolysis constantly comment on this source of loss, which is greatly increased as the temperature is raised, probably owing to the increased solubility of sodium or, in the case of the Downs cell, sodium–calcium alloy in the electrolyte.[26]

Some workers claim that the metal in such circumstances disperses itself in the molten salt in the form of a fog or pyrosol[79] whilst others state that the effect may be attributed either to true solution,[81] or to the formation of a subhalide at high temperatures:-[82]

$$CaCl_2 + Ca \rightleftharpoons 2CaCl.$$

Lorenz and Winzer found that the solubility of sodium in fused sodium chloride is 4·2 and 15·2 weight-% at 800°C. and 850°C. respectively, whilst at slightly higher temperatures the metal phase and the salt phase become completely miscible.[83]

Recent determinations on the equilibria between molten sodium and molten sodium chloride have given the following figures:-[84]

Temperature °C.	Salt phase Mole % Sodium
803	2·4
809	2·8
826	4·9
990	10·2

Evidently the equilibrium concentration of sodium increases very rapidly as the temperature rises.

In the case of the system calcium–calcium chloride, the components form a eutectic containing 1 mole % of calcium at 767°C.[81]

Solubilities of sodium in sodium chloride–calcium chloride melts are given in Table VI.[79,83]

TABLE VI.- SOLUBILITY OF SODIUM IN SODIUM CHLORIDE–CALCIUM CHLORIDE MELTS

Salt Phase Molecular %		Metal Phase Molecular %		Sodium + Calcium as wt. % Sodium
Sodium Chloride	Calcium Chloride	Sodium	Calcium	
Solubility at 700° C.				
33·5	66·5	99·25	0·75	3·4
33·6	66·4	99·31	0·69	4·7
46·6	53·2	99·26	0·74	4·6
57·2	42·8	99·44	0·56	4·5
66·2	33·8	99·48	0·52	4·3
65·8	34·2	99·56	0·44	4·2
Solubility at 600° C.				
47·3	52·7	98·80	1·20	3·3
46·5	53·5	99·09	0·91	2·7
55·8	44·2	99·51	0·49	2·7
Solubility at 500° C.				
48·1	51·9	99·49	0·51	0·4
48·4	51·6	99·12	0·88	0·6
49·4	50·6	99·06	0·94	1·2
48·0	52·0	99·13	0·87	0·4

It has been said that perhaps the greatest difficulty confronting experimenters in the electrolysis of fused sodium chloride is the solution of sodium in fused halide mixtures at temperatures above 700° C.[26] The advantage of operating at a lower temperature is clearly illustrated by the results.

A device for the temperature control of fused electrolyte cells consists of a heat transfer unit employing a vaporizable liquid metal. A sealed tube containing sodium is partially submerged in the electrolyte. The sodium evaporates and condenses on the colder upper portion of the tube where heat is lost by radiation, and runs back into the lower portion of the tube, thus providing regenerative cooling.[26a]

Decomposition Voltage of Sodium Chloride and Calcium Chloride.

The following values for the decomposition voltage of sodium chloride have been obtained by measuring the current flow across fused sodium chloride between graphite electrodes with gradually increasing voltages:-[85,86]

Temperature	835° C.	870° C.	970° C.
Decomposition voltage	2·6	2·55	2·4

Cambi and Devoto[87] determined the decomposition voltage by measuring the electrometric force immediately after cessation of the electrolysis, and obtained results which differ appreciably from the above. They claim that their results are in agreement with the known physical data for chlorine and sodium, and attribute Neumann's low results to depolarization. They also found that the decomposition voltage varied according to the nature of the cathode, as will be seen from the following results:-

Temperature	800°C.	850°C.	900°C.	950°C.	1000°C.
Decomposition voltage, using a copper cathode	3·254	3·180	3·107	3·033	2·96

continued on following page.

Temperature	800° C.	850° C.	900° C.	950° C.	1000° C.
Decomposition voltage, using an iron cathode	3·200	3·129	3·058	2·987	–
Neumann, using a graphite cathode	2·65	2·58	2·51	2·43	2·36

By extrapolation from the results given, the decomposition voltage of sodium chloride at 600°C. is 2·93 V. (Neumann) or 3·48 V. (Cambi and Devoto). In the case of calcium chloride the following figures are given:-[67]

Temperature	780° C.	804° C.	830° C.
Decomposition voltage	3·314	3·228	3·18

By extrapolation, the decomposition voltage at 600° C. is 3·67 V.

Data have been recorded on the density, viscosity, specific conductivity and surface tension of sodium chloride–calcium chloride melts at temperatures varying from 500° to 1000° C. and from 0 to 100% of calcium chloride.[88-88d] and on the density of the binary electrolytic bath sodium chloride–calcium chloride for varying proportions of the salts over the temperature range 550–850° C.[89] The mechanism of the cathodic process in the electrolysis of a fused sodium chloride–calcium chloride melt, using an iron cathode, has been studied.[89a]

The effect of small amounts of potassium chloride on the conductivities of calcium chloride–sodium chloride mixtures has been studied.[88e,f]

Influence of Electrolyte Impurities on Electrolysis.

Little information has been published regarding the influence of impurities in the electrolyte on Downs cell operation. The presence of soluble oxygen-containing compounds appears to be detrimental to cell efficiency, however, as such impurities are decomposed at the anode during the electrolysis with the liberation of oxygen or other harmful substances which may attack or corrode the active surface of the anode with consequent increase in cell voltage. Alternatively the impurities may form soluble secondary substances which are in turn decomposed by the current, thus initiating a cycle which may reduce the current efficiency to a small fraction of that attainable when such impurities are absent.[90]

Danneel's observations on the influence of oxygen-containing compounds in low melting-point sodium chloride baths containing fluorides[27] are probably equally applicable to calcium chloride–sodium chloride melts. He remarks that it is desirable to avoid oxidation of the sodium produced during the electrolysis. When sodium oxide is formed it tends to dissolve in the electrolyte where it is electrolyzed:-

$$2Na_2O \rightarrow 4Na + O_2.$$

The oxygen is liberated at the anode where it combines with the graphite of the anode to give carbon monoxide, thus accelerating anode wear and reducing cell life. The carbon monoxide so produced also tends to react with chlorine to give phosgene.[27]

Dissolved sodium oxide in the electrolyte also attacks the silica of the cell lining to give a silicate which in turn is electrolyzed according to the equation:-[27]

$$2Na_2SiO_3 \rightarrow 4Na + 2SiO_2 + O_2.$$

The silica and oxygen are formed at the anode, where the oxygen reacts to give carbon monoxide and the silica is reduced to silicon, which ultimately appears as silicon tetrachloride in the chlorine evolved during electrolysis.[27]

According to a patent, when sodium is being produced by the electrolysis of fused salt baths containing substantial amounts of sodium chloride, the bath may be kept free from sodium oxide by adding small quantities of a metal, or a metal compound, which can react with the sodium produced or with its oxide to give a compound insoluble in the cell bath.[91,92] Thus, alumina may be used to keep the cell bath substantially free from oxide.[91] The addition of aluminium or calcium to the bath feed compartment has also been proposed;[90] in this case the oxygen compounds formed are only partially soluble in the molten electrolyte and can be sludged out of the cell. Impurities may also be removed by a secondary electrolysis of the cell bath.[90]

Downs Cell Sludge.

The use of a sodium chloride–calcium chloride bath in the Downs cell has the advantage of permitting electrolysis at a comparatively low temperature. There are, however, accompanying disadvantages attached to the use of such an electrolyte mixture, and one of the most serious arises because the equilibrium mixture of sodium and calcium produced in the cell contains several per cent. of calcium. Moreover, sodium chloride is slightly soluble in molten sodium at the operating temperature and the metal is therefore likely to contain small amounts of the salt phase in solution.[29,48,84] These impurities are largely eliminated by cooling the metal mixture to 100–120°C., before it leaves the cell[48] (see also page 343). The substantially pure sodium thus obtained is further purified by filtration to give sodium containing only about 0·04% of calcium, and the residue from this filtration is a mixture of sodium with considerable quantities of calcium metal, generally termed 'Downs cell sludge'.

The disposal of this sludge presents a considerable problem, and a number of patents have been filed describing procedures or devices for reducing the calcium content of the sodium leaving the Downs cell and so minimizing the amount of sludge produced on subsequent filtration.[51-53,56-61]

One claims that if the sodium is filtered in the molten state through a filter medium across which a pressure difference is maintained, satisfactory filtration can be achieved with a relatively coarse filter medium having openings which are larger than a substantial proportion of the alkaline earth metal particles present in the sodium.[62-63a]

Sodium may be recovered by introducing the sludge into a bath of molten salt having a density higher than that of sodium, containing calcium chloride together with over 30% of sodium chloride, at a temperature of 600–800°C.[67-69] Reaction takes place between sodium chloride and calcium to give sodium metal which, together with the sodium already present in the sludge, floats to the top of the bath and may be collected. If the operation is carried out efficiently the sodium should contain less than 0·1% of calcium.

The purification may also be conveniently accomplished by introducing the sludge into a fused mixture of sodium chloride and calcium chloride which is undergoing electrolysis in an electrolytic cell such as the Downs cell, and this appears to offer a simple means of disposal.[70-72]

An apparatus for the separate recovery of sodium and calcium by distillation from Downs cell sludge has been described.[93a]

It has also been proposed to dispose of the sludge by mixing it with material containing silica and heating in air to form sodium silicate, calcium oxide and silica.[93]

Patents have been taken out for the recovery of the calcium content of such sludges by treating them with an excess of an organic compound such as ethyl or methyl alcohol, which combines with both sodium and calcium but which initially reacts preferentially with substantially all the sodium to yield sodium ethoxide or methoxide which remains in solution. When the sodium is dissolved the sodium alkoxide solution can be filtered off before the calcium is appreciably attacked, and the residue dried to give calcium metal of 80–95% purity in a yield of 80–90%. The presence of small amounts of water in the alcohol is said to facilitate control of the reaction.[94,94b-e] Calcium has also been recovered by electrolysis of sludge in a monohydroxylhydrocarbon such as ethyl alcohol.[94a]

An apparatus has been patented for the safe disposal of Downs cell sludge by treating it in a column with an aqueous solution of the hydroxides of calcium and sodium.[95,96] The sludge is fed continuously at the bottom of the column, the subsequent reaction liberating hydrogen which keeps the system in violent agitation and continuously carries the metal to the top of the column, where a disengaging space is provided to separate the hydrogen from the strong hydroxide solution, which is removed in part, while the remainder of the solution is recycled. Weak hydroxide or water is added continuously at the bottom of the column.

Other Processes for the Manufacture of Sodium by Electrolysis of Fused Sodium Compounds.

In addition to the Castner, Ciba and Downs cells, a number of other cells for the production of sodium by electrolysis of fused sodium compounds have been patented. It has been proposed to withdraw the cell products separately in vapour or gaseous form.[50,97] It has been proposed to electrolyze fused sodium carbonate in a bath containing 64·4% of sodium carbonate and 35·6% of sodium chloride which melts at 600° C. The sodium chloride is not decomposed during the electrolysis which, may be carried out in a Castner cell.[98] A patent has been taken out for the production of sodium by electrolyzing a melt consisting chiefly of sodium borate in the presence of a molten alloy of sodium with tin or metals having similar properties, the alloy serving as the anode.[99] When sodium is prepared by the electrolysis of fused sodium nitrate, trouble arises owing to the migration of the nitrate ion from the anode compartment to the cathode compartment of the cell, where it reforms sodium nitrate by reaction with the metallic sodium liberated at the cathode, with consequent loss of cell efficiency. A process has been patented in which the electrolysis is carried out in the presence of sodium carbonate or sodamide, whereby migration of the anion is avoided, and its detrimental results suppressed.[100] These compounds react with the oxides of nitrogen liberated at the anode, producing gaseous carbon dioxide or ammonia which, being inert to the electrolyte, may be recovered together with the oxygen formed during the electrolysis. None of the foregoing processes seem to have met with any success on the technical scale.

PRODUCTION OF SODIUM ALLOYS BY ELECTROLYSIS

In spite of persistent efforts, the manufacture of sodium by the electrolysis of fused sodium chloride in the presence of a molten lead cathode never achieved any permanent success, and, since the advent of the Downs cell, has been regarded as obsolete. When sodium is utilized in the manufacture of tetraethyl lead, however, the metal must be in the form of a sodium lead alloy which has to be specially prepared from the metallic sodium. It is therefore possible that, for this purpose at least, an electrolytic route which produces a sodium-lead alloy in a single state may compete successfully with a two-stage process which involves making sodium in a Downs cell and then alloying it with lead, and it is interesting to note that such a development has occurred in Germany in recent years.

During the 1939-45 war a plant was erected at Heydebreck, Germany, by the I. G. Farbenindustrie for the manufacture of lead-sodium alloy by an electrolytic route developed by Hamprecht.[7,101]

The electrolysis was carried out using a graphite anode and a molten lead cathode with an electrolyte consisting of a mixture of sodium and potassium chlorides, melting about 700°C. The plant consisted of six cells each 2·5 metres wide and 4·5 metres long. The sodium chloride, previously melted in an electric furnace, was fed to the cells at the rate of approximately 50 kg. per cell per hour and a make-up of about 1·7 kg. of potassium chloride was also required. The cells were fed with approximately 160 kg. of lead per cell per hour and each cell produced approximately 4 metric tons per day of a lead–sodium alloy containing 10% of sodium, at a current efficiency of 80% and a voltage of 3·5 with an energy consumption of 8 kWh. per kg. of sodium. The chlorine produced by the cells was utilized in the production of ethyl chloride.

The lead–sodium alloy thus produced contained small amounts of potassium, and it is said that the presence of about 1% of potassium considerably increases the yield of tetraethyl lead obtained in the ethylation process.

It is claimed that the direct electrolytic production of a lead–sodium alloy for tetraethyl lead manufacture is economically advantageous and utilization of the alloy was confined to this purpose. Hamprecht showed that sodium hydroxide containing more than 99% NaOH could be made from the alloy, but no attempt appears to have been made to isolate metallic sodium. More recently the production of a sodium-lead alloy using a thin stream of molten lead as cathode in a cell for the electrolysis of fused salt has been developed by Szechtman.[101a,b] A cell for the manufacture of a sodium-lead alloy by electrolysis of fused sodium chloride has been described.[101c] A patent describes the preparation of sodium-lead alloys by the electrolysis of sodium chloride–sodium fluoride–potassium fluoride melts using a molten lead cathode.[101d] A sodium-lead alloy is produced by dissolving lead in sodium amalgam which has been prepared in an electrolytic cell with a mercury cathode, and then removing the mercury by distillation.[101e] Little further work appears to have been done on the preparation of sodium alloys by electrolysis. According to a patent an indium–sodium alloy may be prepared by the electrolysis of indium oxide in fused sodium hydroxide at about 425° C.[102]

THE PURIFICATION OF SODIUM

Commercial grade Downs cell sodium attains the remarkable degree of purity of 99·95%,[1] and in the United States an even purer grade of metal is available.[2] Thus, commercial sodium is likely to be suitable for all ordinary laboratory purposes without further purification. There are, however, occasions, as for example when the sodium is required for determinations of the physical properties of the metal or for use as a liquid metal in a heat transfer system, when the presence of even traces of impurities may be deleterious. A considerable amount of work has accordingly been devoted to methods of purifying the metal.

One of the simplest methods of purifying sodium is by filtration.[1-6] The operation is carried out, preferably in an inert atmosphere, at a temperature at which the impurities in the sodium are in the solid state and the sodium itself is molten. It appears to be advantageous to allow the molten metal to age before filtration.[1]

Thus, in a method attributed to Bunsen, sodium is sealed under nitrogen in one compartment of a glass vessel divided into two compartments separated by a sieve. The sodium is heated in the first compartment till it has reacted with any water, oxygen or carbon dioxide in the nitrogen and is then filtered through the sieve into the second compartment, where it is allowed to solidify. The sieve retains any carbonate or hydroxide present in the sodium. The method is applicable to the purification of small amounts of sodium in the laboratory.[5]

It is stated that when molten sodium containing excess of sodium oxide is passed through a filter, which may be fabricated from sintered stainless steel or composed of several layers of fine-mesh stainless steel gauze, a filter cake consisting of sodium oxide is built up, and that continued cycling of the sodium through such a bed will finally give a filtered sodium almost completely free from oxide.[1]

Sodium oxide, carbonate and chloride are generally present in appreciable amounts in commercial sodium, and the extent to which these impurities can be removed by filtration obviously depends on their respective solubilities in the molten metal. Several laboratories have produced figures for the solubility of sodium oxide and sodium hydroxide in sodium and also in sodium-potassium alloys.[1,7a] Thus, the solubility of oxygen in sodium has been determined over the temperature range 130–540°C. and in sodium-potassium alloy over the range 20–176°C. using apparatus of both glass and stainless steel, and the sources of error encountered when using glass apparatus have also been investigated.[7] It is reported that the solubility of oxygen in sodium is 10 p.p.m. at 98°C. and 130°p.p.m. at 300°C.[8]

The solubility of sodium carbonate in molten sodium has been determined over the temperature range 150–385°C. The solubility is given as 0·002 and 0·027 wt.-% of sodium carbonate at 150° and 385°C. respectively.[8a] The apparent oxygen content (total alkalinity calculated as oxygen) of sodium saturated with sodium monoxide, sodium carbonate and sodium hydride for temperatures up to approximately 400°C. has also been determined and is found to be low at temperatures just above the melting point of sodium.[1b]

Sodium hydride is another impurity which is likely to be present in unpurified sodium. Solubility determinations show that the solubility of the hydride is 4·29 wt.-% of sodium hydride at 445°C. and falls to 0·005 wt.-% at 250°C.[8a,1d] Removal of sodium hydride by filtration should therefore be feasible.

The following figures are given for the solubility of sodium chloride in molten sodium.[9]

Temperature °C.	Mole % Sodium Chloride in Molten Sodium
550	0·12

continued on following page.

Temperature °C.	Mole % Sodium Chloride in Molten Sodium
750	1·8
781	2·2
790	2·9
832	4·2
874	5·8

No determinations appear to have been carried out at lower temperatures, but the above results suggest that the solubility falls off rapidly with decreasing temperature and that the amount of sodium chloride in solution in molten sodium at temperatures slightly above the melting point of the metal is likely to be very small.

Sintered stainless steel filters with a nominal pore size of 5–10 microns have been found satisfactory for the purification of sodium by filtration.[2]

An apparatus for the filtration of sodium has been patented.[10a]

In the studies of surface properties of liquid sodium, as for example surface tension and contact angle, it is essential to maintain a perfectly clean surface on the molten metal for long periods of time and this involves the use of an inert gas atmosphere of high purity. Molten sodium surfaces are highly sensitive to traces of moisture and readily become clouded in the presence of this impurity. When using an inert gas atmosphere of argon dried first by magnesium perchlorate and then by phosphorus pentoxide it was found that a molten sodium surface clouded over in 1 hr., whereas when the argon was purified by passing it through a molecular sieve, the surface of the metal remained bright indefinitely. The effect of the molecular sieve is attributed to the removal of moisture from the argon, and not to the removal of oxygen.[11a]

Molten sodium may be freed from oxygen-containing sodium compounds such as the oxide or hydroxide by a process that has been called 'gettering' by analogy with the removal of oxygen and other gases in vacuum technology.[1,10] This consists in adding to the molten sodium substances which reduce the sodium oxides to sodium metal, and at the same time form an oxygen-containing compound insoluble in molten sodium. It is essential to heat the mixture of sodium and the getter to such a temperature that reaction between the oxide and the getter will take place. When the reaction is completed, the molten sodium is cooled to a temperature just above its melting point and then filtered to remove the insoluble compound formed by the gettering process, thus giving a filtrate of oxygen-free sodium. Magnesium and calcium have been recommended as gettering materials.[1,10] The oxygen content of a sample of calcium gettered sodium has been given as probably less than 0·005 wt.-%.[10]

A cold trap on the system might be expected to remove getter oxides, but no information appears to be available on the performance of cold traps in this way.[11b] A second class of gettering agents consists of those which are themselves essentially insoluble in sodium or sodium–potassium alloy and which reduce sodium oxides to the getter oxide which is also insoluble in the molten metal. Materials used in this way are titanium, zirconium and uranium.[11b-m] In practice the getter material in massive form is supported mechanically in the stream of molten metal and the getter oxide forms on the surface of the getter. A very heavy coating of oxide may lead to flake off and be carried round the system and settle out at a low point with consequent danger of blockage. There is no evidence that the chromium in stainless steel lowers the oxygen content of molten sodium significantly, although it is stated that some reduction of oxide by chromium does take place.[11b]

Small amounts of potassium can be removed from molten sodium by digestion with graphite at 300°C., followed by filtration. The lower limit of potassium removal in this way is 30 p.p.m.[11b]

According to a patent, sodium containing small amounts of an alkaline earth metal such as calcium can be purified by subjecting it in the molten state to the action of an oxidizing agent such as air or sodium hydroxide at a temperature not less than 350° C. The alkaline earth metal is converted into the oxide, which may then be separated from the molten sodium by filtration or other means.[11] The purification of sodium containing larger amounts of calcium has already been discussed. (see page 352).

The removal of impurities from molten sodium and sodium-potassium alloys by the use of a cold trap has recently found extensive application in heat transfer systems.[11c-m]

Cold trapping is essentially a method of removal of impurities based on the solubility-temperature relationship, and in its simplest form consists of a surface on which precipitation takes place by virtue of its being colder than the saturation temperature of the impurity.[11c]

Cold traps may be classified as natural and forced circulation traps. A natural circulation trap can be merely a cold steel end somewhere in the system, although it is generally a vessel with means of draining. Delivery of impurities of the circulating stream of molten metal to the cold surface of the trap is dependent on natural circulation brought about by turbulence at the entrance of the trap, and diffusion of the impurities into the trap. In the forced circulation trap, a portion of the circulation metal (generally 1-2%) is by-passed and pumped over a cold surface, thus giving more intimate and rapid mixing than is possible with a natural circulation trap. A typical cold trap operates at a temperature of about 150° C. with a main stream temperature of about 250° C.[11c]

The basic function of the cold trap in heat transfer systems is to remove sodium oxides, and vessels packed with stainless steel wool or stainless steel mesh will give an exit stream with an oxide content closely approaching the solubility of the oxide at the cold trap temperature. Ordinary steel work is not satisfactory and tends to break up.[11c]

In addition to oxides, materials which have a sharply changing temperature solubility in sodium such as antimony and silver are also removed. Metallic impurities such as iron, chromium, cobalt and nickel also appear in cold traps in some quantity.

The mechanism of the transport of these impurities has not, however, been determined.[11c]

The removal of hydrogen as sodium hydride from molten sodium by means of cold trapping has been demonstrated.[11d]

The impurities deposited in the cold trap can be returned to the main stream by heating the trap and the oxygen content of the circulating metal can be maintained at any desired level by adjusting the cold trap temperature. The design and performance of cold traps has been discussed.[11c-h]

Oxide solubility variation with temperature is also made use of in the plugging indicator, a device for measuring the oxide content of liquid sodium and sodium potassium alloys systems in a semi-continuous manner without removing samples from the system. A portion of the main stream is directed through a by-pass loop containing a cooling jacket, an orifice plate and a flowmeter. In operation the temperature of the by-pass stream is successively reduced by increasing the coolant flow until it falls slightly below the value corresponding to saturation of the liquid with oxide. At this point, solid oxide precipitates out, plugging the orifice and thus reducing the by-pass flow as indicated on the flowmeter. By noting the temperature at which this takes place, the saturation limit, and hence the oxide content, of the liquid can be determined.[11i] Plugging can however also result from other insolubles such as metal chips, weld slag, calcium oxide and residues produced by the reaction of sodium with hydrocarbons, and to obtain accurate oxide determinations these impurities must be absent.[11d]

The purification of sodium by distillation has been studied.[1,12-16] It is said that most of the impurities in sodium, with the exception of sodium oxide, can be removed by distillation, which may be carried out in glassware under reduced pressure,[1] or in metal equipment at normal pressures.[1] It may be desirable to reject the light and heavy fractions of the distillate.[14] The following analysis has been given for vacuum-distilled sodium: sodium 99·995%, boron 40 p.p.m., potassium 20 p.p.m., oxygen 5–10 p.p.m.[15] A simplified procedure for the simultaneous preparation of several samples of twice distilled sodium in Pyrex glass ampoules has been described and it is claimed that the product is entirely free from oxide or other contaminants.[16] There seems, however, to be some doubt as to the extent to which sodium oxide can be removed by distillation. Thus, it is claimed that experiments with irradiated sodium oxide have shown that no trace of sodium oxide distils at 600°C. in vacuo:[17] on the other hand it is stated that the oxygen content of triple-distilled sodium is 0·008 ± 0·003%.[18] Another author gives the oxygen content of distilled sodium as 0·0005–0·0010%.[15]

The iron content of double-distilled sodium is stated to be very similar to that of triple-distilled sodium: colorimetric determinations give the iron content of the latter as 1 part in 8×10^6 parts of sodium.[19]

The rates of reaction with air of filtered and distilled sodium have been compared.[19a]

One patent describes a glass which resists sodium vapour and therefore might by suitable as a constructional material for sodium distillation apparatus.[20]

The feasibility of sodium purification by distillation is discussed. It is concluded that sodium chloride and sodium sulphite can be separated by distillation at 450°C. Magnesium is not likely to be completely eliminated by distillation. The vapour pressures of manganese, silver, aluminium, beryllium, copper, nickel, iron and boron favour quantitative retention in the undistilled residue. Some doubt appears however to exist regarding the possibility of completely eliminating calcium and silicon by distillation.[20a] A combined filtration and vacuum distillation unit for the purification of sodium has been described. Operating data are given.[20b]

Sodium containing mercury may be purified by passing it in the molten condition over calcium at 380°C.[6]

Other methods of purification have been suggested. It is claimed that sodium can be purified by melting it repeatedly in contact with petroleum.[21] Patents describe the purification of sodium by heating it in a steel tube in contact with sodium chloride or other inert salts.[22,23] Another patent describes a process for the purification of sodium whereby the metal is dissolved in liquid ammonia, the solution filtered to remove the undissolved impurities, and the sodium recovered by removing the ammonia by evaporation.[24]

FORMS OF SODIUM

Sodium may be conveniently handled and applied in the form of dispersions.[25-27b] In systems in which sodium is insoluble, reaction takes place only at the sodium surface and the rate of reaction is a direct function of the surface available. By the use of dispersing agents, molten sodium can be emulsified in inert liquids, and a large surface area thus made available. It is frequently found that surface films of insoluble reaction products build up on a sodium surface and tend to isolate it from further access to reagents. When small particles of sodium are used, a point is reached, in the 1 to 10 micron particle size range, when reaction of the sodium is complete before the inert film is thick enough to hinder reaction seriously. Techniques for producing dispersions of sodium in inert liquids have been described.[25-27h]

Sodium in the form of a dispersion in petroleum jelly is prepared by heating a mixture of the two ingredients, normally containing from 10–30% of the metal, to a temperature at which both components are fluid and then subjecting the mass to violent agitation while cooling. The petroleum jelly protects the metal so well that the dispersion may be immersed in cold water without any apparent evolution of hydrogen taking place.[27i]

More recently sodium has been produced in the form of 'high-surface' sodium.[28] This term is applied to films of sodium approaching colloidal dimensions spread over inert solids of high surface area to give a free flowing product. It is claimed that sodium in this form is advantageous for the preparation of finely divided metals, for the purification of hydrocarbons and ethers and for the preparation of inorganic and organic derivatives. In these applications high-surface sodium affords easy control of reaction rates at temperatures below and above the melting point of sodium, and also eliminates the risks attending the use of inflammable dispersion materials. It is also claimed that induction periods are reduced or eliminated, and that the products may be prepared in a finely divided and highly reactive state. In addition, yields are high, and the use of high-surface sodium lends itself to continuous operation. The following solid carrier materials have been used in a finely divided form for the preparation of high-surface sodium:-

1. Activated alumina
2. Activated coconut carbon
3. Iron powder
4. Colloidal carbon
5. Sodium chloride
6. White sand
7. Sodium carbonate
8. Zirconium oxide

The amount of sodium that can be absorbed while maintaining the carrier material as a free flowing product depends on the total surface area of the solid carrier. Thus, salt may carry from 2–10%, soda ash 10% and alumina 20–25% of sodium. In the case of activated or colloidal carbons, however, the sodium content may exceed 30%. The free flowing characteristics can be maintained at temperatures up to the boiling point of sodium, provided that the carrier remains stable at such temperatures.

The reactivity of high-surface sodium systems with air and water have been studied.[28] Sodium–carbon systems become heated to redness on exposure to air owing to the oxidation of the sodium and the carbon; other carriers for sodium which are combustible, such as finely divided metals, may ignite. On the other hand sodium dispersed on non-inflammable carriers such as alumina, salt, soda ash etc. becomes heated on exposure to the atmosphere but does not ignite, and frequently such systems are found to react with water in a comparatively gentle manner with only a rapid evolution of hydrogen which does not ignite or explode. The preparation of high-surface sodium, and a number of its applications, have been described in detail.[28]

The preparation of colloidal sodium has been described.[28a-c]

Sodium is also available in the form of spheres about 0·2 to 2 mm. in diameter, generally termed sodium sand.[29] This product, made by shaking or stirring molten sodium in an inert hydrocarbon oil, provides a convenient means of introducing sodium into reaction zones in definite amounts.[29] Metal in the form of slightly larger spheres of 0·5 to 1·0 in. diameter is also available, and is termed 'sodium marbles'.[30] One patent describes the production of sodium in the form of an extruded continuous core, small and substantially uniform in cross section, enveloped by a thin continuous tightly fitting sheath of another metal resistant to oxidation, such as lead. The sheath may be crimped at the ends to seal the core from the atmosphere.[31]

Sodium may also be prepared in a subdivided form by grinding the metal in an inert atmosphere at temperatures below 0°C., and preferably below −90°C.[32]

A highly pure form of sodium, described as 'Argon grade' sodium, has recently become available in the United States.[2,33] This material, which is filtered and packed under an atmosphere of argon, is said to be free from oxygen or nitrogen, and is recommended for use where traces of such gases are considered to be deleterious.

A new reactor-grade sodium which contains less than 25 p.p.m. of calcium has recently become available, and is now being used in atomic power systems in America.[33a]

HANDLING, STORAGE AND AVAILABILITY OF SODIUM

The handling and storage of sodium has been dealt with by a number of authors.[34-41] Among the subjects discussed in detail are fire prevention and fire fighting, cleaning of contaminated apparatus and equipment, disposal of waste sodium residues and protective clothing for personnel handling sodium. A safe technique for handling sticks of sodium on a large scale has also been described.[40] In general it may be said that the safety precautions desirable with sodium are well known and need not be considered further here. Attention is, however, drawn specifically to the following hazards, the significance of which did not appear to be appreciated when the original Treatise was published.

Sodium and the other alkali metals form detonating mixtures with organic halogen compounds and also with solid carbon dioxide and on this account carbon tetrachloride must not be used to put out sodium fires.[41,42] Such fires are best dealt with by smothering them with dry sand, or better with dry soda ash or salt. Sodium bicarbonate must not be used in place of soda ash.[1,41] The use of a mixture containing 704 parts of sodium chloride, 20 parts of pitch and 16 parts of graphite for extinguishing sodium fires has been patented.[43] Other alkali or alkaline earth metal chlorides may be used in place of sodium chloride.

Dangerous mixtures are formed by the partial oxidation of sodium. Thus, when molten sodium is exposed to air, the surface of the metal rapidly becomes coated with a film of oxide or hydroxide, and as the oxidation proceeds this film becomes a viscous mixture of metallic sodium with oxidized sodium compounds.[41] This mixture tends to ignite easily and is dangerous. Similarly pieces of dry sodium exposed to air for a period may acquire a film which should be removed with a knife before returning the metal to an enclosed space, since the film reacts slowly with sodium metal evolving hydrogen which may give rise to fire or explosion.[41] Data on the flammability of sodium alloys at 600–800°C. are available.[42a,b]

The disposal of sodium wastes and residues has also been investigated. A novel method for the safe and rapid disposal of large quantities of sodium has been described.[44,44a] Molten sodium at 350°F. is discharged under a minimum depth of 10 ft. of water through an annular orifice with a free area of 0·226 sq. in., at flow rates of approximately 90 lb. per minute. The hydrogen produced by the reaction does not ignite, and little sodium oxide smoke is formed. Sodium detonates with great violence when thrown on ice.[44b]

Liquid ammonia and ammonia–ammonium chloride washes are effective for removing sodium and sodium sludges from a liquid metal system.[44d] Cleaning has also been accomplished by the use of a mixture of water vapour and inert gas.[44c]

The fire and health hazards of radioactive sodium include all those mentioned for ordinary sodium with an additional radiation hazard. When sodium is used as a reactor coolant, radioactive ^{24}Na tends to build up to an equilibrium value, and this is a very powerful beta and gamma emitter having a half life of 14·8 hr. The known hazards of this isotope have been classified, and design of equipment of systems producing the isotope, protective clothing, fire fighting, first aid equipment, disposal of radioactive sodium waste, and regulations governing shipping of radioactive sodium in U.S.A. have been discussed.[44e]

A precision sodium cutter has been described.[45]

An account of the resistance of materials to corrosion by liquid sodium over a wide temperature range is given.[46–46z] Static corrosion tests at temperatures between 400° and 500° C. for a period of 1 month, using sodium with a probable oxygen content of 0·005–0·01%, show excellent corrosion resistance for Armco iron, beryllium, nickel, Monel metal, numerous stainless steels and zirconium. In the case of aluminium and many aluminium alloys resistance is poor, but that of aluminium bronze is excellent. Steels are quite satisfactory over longer periods. Thus, liquid sodium has been transferred continuously for many years in a mild steel pipe without any sign of deleterious attack on the pipe wall, and clean liquid sodium has been handled in stainless steel at 500°C. for periods up to three years without failure of the container. Static corrosion tests have also been carried out using calcium 'gettered' sodium with a probable oxygen content of less than 0·005%. The corrosion of iron by sodium contaminated with oxygen has been investigated.[46s] The mechanism of liquid sodium corrosion has been discussed and is said to be largely a solution phenomenon.[47] The effect of impurities, temperature, temperature gradient and flow velocity on corrosion mechanism have been studied.[47–47c] Non-metallic materials such as beryllia, zirconia, magnesia, alumina, molybdenum disilicide and numerous metal-ceramics are not attacked by sodium when they are in a sufficiently dense form, but are penetrated and disintegrated if porous.[46] The corrosion of molybdenum wire at 1500°C. in sodium vapour has been studied.[48]

Sodium does not react with glass at temperatures below 300°C., but above this temperature Pyrex glass is rapidly attacked.[46] Extensive tests have been carried out to determine the protective qualities of various items of safety equipment in contact with hot sodium.[49]

The handling of sodium in molten form in heat transfer systems has been described, and information is available on the pumping of liquid sodium by means of mechanical and electromagnetic pumps.[49–54i] A novel pump for the continuous feeding of sodium at metered rates has also been described.[54]

The handling and storage of sodium–potassium alloys are discussed under Potassium (see Suppl. 3).

For large scale industrial use in Great Britain, sodium is generally cast in the form of blocks weighing 12½–15 lb. A process for the continuous casting of sodium has been patented.[54j] There is also a considerable tonnage of 3½ lb. blocks, pellets and sticks, and the metal is generally shipped in airtight containers in preference to the older practice of shipping under naphtha.[55] In the United States sodium is also shipped in rail tanks.[37] The tank car used has a capacity of 40 tons and is equipped with pipes welded to the inner shell for circulating heating or cooling oil between the inner and outer shells. As the tank is being filled with sodium under an

inert atmosphere of nitrogen, cooling oil is circulated through the system, thus solidifying the sodium: when filled the tank is sealed under nitrogen. When the tank arrives at its destination, the sodium is remelted by circulating heated oil and the molten metal is withdrawn by applying a vacuum to the unloading line and adding nitrogen to the tank as emptying proceeds. The low melting point, low specific gravity, high heat conductivity of sodium and the large scale demand for the metal make this shipping practice feasible, and this is probably the only case in which a metal is shipped in such a manner.

The storage of sodium in capillary tubes has been described in a number of patents.[56,57]

No adhesion occurs between sodium and polythene, and metal encased in that material may be stored without deterioration.[57a] A ferrous metal container for sodium, having a phosphatized inner surface which prevents adhesion of sodium to the container walls, has been patented.[57b]

THE USES OF SODIUM

In the year 1888, H. Y. Castner started to manufacture sodium on the commercial scale at Oldbury, England, using a modified form of Deville's process.[1] The product was utilized in an adjacent plant for the manufacture of aluminium by the reduction of aluminium chloride. This new route to aluminium resulted in a substantial reduction in the price of that metal, and the Castner plant ran successfully for over two years, during which it produced over one hundred tons of aluminium. The process had scarcely become

Refs. p. 373

established, however, when the introduction of the present electrolytic method of aluminium manufacture rendered the use of sodium for this purpose unnecessary, and this greatly reduced the demand for the latter metal. Thus, Castner, who at that time had recently developed a cell for the manufacture of sodium by the electrolysis of fused sodium hydroxide, found himself with a process for making sodium but no market for his product. The future prospects for sodium must have seemed very black indeed, but Castner lost no time in turning his attention to other possible uses for the metal, and it is no small tribute to the inventive genius of that remarkable man, that he very quickly succeeded in developing two new outlets for sodium, based on the manufacture of sodium cyanide and sodium peroxide. As might well be expected a number of further uses for the metal have been developed since then, notably in the manufacture of tetraethyl lead and alkyl sulphates, but substantial amounts of sodium still continue to be used in cyanide and peroxide manufacture.

The following figures are given for the amounts of sodium consumed by various usages in the United States:-

Use	Million pounds per year		
	1947[2]	1948[2]	1953[3]
Tetraethyl lead	66	90	137
Sodium cyanide	25	32	40–50
Sodium alkyl sulphate	25	32	50
Sodium peroxide	7	7	7–10
Sodium hydride	2	2	–*
Indigo synthesis	2	2	–*
Miscellaneous	6	6	–*
	133	139	–*

* No figures available

No comparable figures have been given for other countries or for world usage.

It will be appreciated that in addition to the major uses listed above the heading 'miscellaneous' covers a very large number of comparatively minor applications of the metal, so that it is not possible here to do more than survey this field in a general manner. For further information on this subject the reader is referred to chemical encyclopædias such as Kirk Othmer[4] and Thorpe,[5] and also to the numerous reviews which have been published on the uses of sodium.[1-3,6-16m]

The production of sodium cyanide still represents one of the major outlets for sodium. Sodium cyanide is manufactured by reaction of sodium with ammonia to yield sodamide, which then reacts with carbon to give sodium cyanamide. The cyanamide reacts in turn with additional carbon to form sodium cyanide: $2Na + 2NH_3 \rightarrow 2NaNH_2 + H_2$; $2NaNH_2 + C \rightarrow Na_2CN_2 + 2H_2$; $Na_2CN_2 + C \rightarrow 2NaCN$. Among the important industrial applications of sodium cyanide are gold extraction,[12] electroplating,[12] case hardening,[12] hydrocyanic acid manufacture[12] and organic syntheses.[12] Sodium peroxide is manufactured by burning sodium in air under carefully controlled conditions.[13] It is a powerful oxidizing agent and is used principally in the bleaching industry as such, and also in the manufacture of bleaching agents such as sodium perborate or percarbonate.[12]

The largest single use for sodium metal is in the manufacture of tetraethyl lead, used as an antiknock compound in petrol,[14] by reaction of a lead–sodium alloy with ethyl chloride according to the equation:-[12]

$$4PbNa + 4C_2H_5Cl \rightarrow Pb(C_2H_5)_4 + 3Pb + 4NaCl.$$

The utilization of sodium in the preparation of tetraethyl lead is responsible for the very large expansion in the demand for the metal during the last thirty years. The advent of the jet engine, which does not use tetraethyl fuels, may have a profound effect on the demand for sodium.[1] Similarly the Ziegler route to tetraethyl lead, which does not use sodium, has threatened the applications for the metal.[1a]

The growth of the synthetic detergent industry has resulted in an increasing demand for large quantities of fatty alcohols.[15,15a] These are prepared by the sodium reduction of the higher fatty acid esters in the presence of a suitable alcohol. Thus, in one process triglycerides are reduced with sodium in the presence of 4-methyl-2-pentanol to yield the sodium salt of the fatty alcohol, which is then hydrolyzed to yield the alcohol and caustic soda. The sodium salt of the sulphonated alcohol is used as a detergent.[15]

Sodium hydride is formed by the reaction of molten sodium with hydrogen at 250–300°C. and can be substituted for sodium in many organic reactions. In recent years a substantial amount of sodium has been used in the preparation of sodium hydride for the descaling and deoxidizing of steels.[17,18] The hydride is prepared by dissolving sodium in a bath of fused caustic soda in the presence of hydrogen, and this gives a bath having a number of advantages over the conventional aqueous acid baths used for pickling. Thus, for example, the sodium hydride process eliminates pitting, hydrogen embrittlement and loss of metal, all of which are objectionable features in acid pickling.

An important outlet for sodium lies in the production of dyes and dyestuffs intermediates. In the synthesis of indigo, the sodium or potassium derivative of phenylglycine is fused with sodium hydroxide or potassium hydroxide, or a mixture of these hydroxides, in the presence of sodamide or sodium. The fusion product, indoxyl, is then hydrolyzed in water and oxidized with air to yield indigo.[19] Sodium may be used in the condensation of ethyl acetate with ethyl oxalate to form ethyl oxalacetate, a raw material used in the manufacture of pyrazolone dyes.[20] The intermediates of the Hansa group of dyes are formed by the condensation of acetoacetic ester, which may be made by reaction of ethyl acetate and sodium, and an amino compound.[12] The metal is also used extensively in the preparation of drugs such as sulphapyridine,[21] sulphamerazine,[21] barbiturates,[22] antipyrine and antimalarials.[12]

Sodium is also used in the synthesis of perfumes. Thus, for example, phenylethyl alcohol, which has an odour of roses, is prepared by the reduction of phenylacetaldehyde with sodium.[12]

Liquid ammonia is an excellent solvent for sodium and solutions of sodium in that medium have been extensively employed for organic reductions.[23-25b] It is suggested that the reduction of hydrocarbons by sodium in liquid ammonia is probably dependent on the addition of the metal at the double bond.[24] Among the reductions which have been carried out in this manner are those of acetylenes to olefines,[26] of phenanthrene to 1:2:3:4-tetrahydrophenanthrene[27] and of benzyl alcohol to toluene.[28]

A number of patents have been filed on the purification of hydrocarbons with sodium or sodium alloys.[29-35] This method of treatment has been applied to vapours from hydrocarbon materials such as cracked distillates,[29] to refined lubricating or other hydrocarbon oils[32] and to hydrocarbons such as indene, butadiene, styrene or piperylene,[33,34] and naphthalene.[35] It has also been proposed to purify hydrocarbon vapours by electrolyzing fused sodium chloride to give a mixture of sodium and sodium chloride which is then brought into contact with the vaporous hydrocarbon material and subsequently recycled to the zone of electrolysis.[36] Sodium is also employed in the polymerization of unsaturated hydrocarbons,[37-37m] and in alkylating and condensing aromatic hydrocarbons.[37k,37l] Comprehensive reviews which describe the uses of sodium in organic chemistry are available.[39b-m]

It is claimed that many of the technical difficulties encountered in the application of sodium to the refining of hydrocarbons have been overcome by the use of sodium dispersions in liquid media.[38] Such refining operations may also be carried out with colloidal sodium adsorbed on inert solids, generally termed high-surface sodium.[39] Thus, sodium dispersions have been used to remove sulphur compounds, including thiophen, from petroleum.[38]

The purification of crude titanium tetrachloride is carried out by distilling the material in the presence of a sodium–lead alloy.[40] The alloy is added to the crude tetrachloride in a concentration of 4–30 parts per 1000 parts of tetrachloride. The vanadium content of the tetrachloride is thus reduced from 0·15% to 0·002% or less.

In recent years the application of liquid metals as high temperature heat-transfer fluids has been the subject of much research and development work.[41,42c] Liquid sodium has many advantages as a heat transfer medium. It has a very high heat transfer coefficient, a low melting point and a high boiling point, does not decompose or polymerize on heating, and in the absence of oxygen or moisture does not attack iron or steel.[41,42] During the 1939–45 war, heat transfer systems using sodium were operated in the United States on a technical scale, one such installation having a capacity of 1,500,000 B.Th.U. per hour.[41] Experimental liquid metal heat-transfer systems using sodium or sodium alloys are discussed in detail by Trocki.[42]

The excellent heat-transfer properties of molten sodium are also utilized in a number of other ways. For example, the valves of some internal combustion engines are cooled by the use of sodium in the hollow stem and head of the valve. The sodium, which is liquid at the working temperature of the valves, is very effective in reducing the temperature of the valve head and the surface in contact with the valve seat, by dissipating heat via the stem. These valves are extensively employed in modern aircraft engines and also in heavy duty buses and trucks.[41,43,44] Sodium is also used as a coolant in the agitator arms used to move shale heated in a retort in order to recover its oil content.[45] In casting magnesium, sodium-filled cores are utilized to facilitate heat dissipation[41] and sodium–potassium alloy baths are used in heat treatment furnaces.[41] The possibility of using sodium–potassium alloys as coolants for vacuum arc melting furnaces in the production of titanium ingots has been examined.[46a]

Sodium is a good conductor of electricity and has been used for this purpose in place of copper. An installation consisting of an iron pipe filled with sodium, with a capacity of 4000 amp., has operated satisfactorily for a period of several years.[46] The weight per unit conductivity was found to be decidedly less than for copper, and when the experiment was carried out in 1930, the cost per running foot of conductor was approximately the same for copper and for a sodium pipe conductor. It was suggested that the use of sodium as a conductor should be limited to permanent installations where high currents at relatively low voltages are transmitted.

There are extensive uses for sodium in the metallurgical field. Thus, the metal is used, generally in the form of an alloy, for the deoxidation of heavy metals such as copper,[47] brass,[48] bronze[47] and iron.[49,49a] It is also employed to modify the structure of aluminium alloys high in silicon, with resultant improvement in mechanical properties.[50-53l] Lead containing small amounts of sodium is used as a bearing alloy with good frictional properties,[54,55] and sodium is employed for the removal of antimony and bismuth in lead purifica-

Refs. p. 373

tion.[56] Sodium has been used to improve the properties of cast iron.[56a, b]

In the purification of heavy metals such as iron, it is convenient to add the sodium in the form of a dispersion in a carbonaceous liquid such as kerosene.[57] The dispersion is directed against the molten metal surface through a small orifice from a container by means of nitrogen pressure. The kerosene burns, but it is claimed that the addition of sodium in this manner is less hazardous than any other common method of addition.

It is said that the addition of sodium to mercury for use in the amalgamation of gold ores improves the recovery of gold, and a similar addition is recommended for increasing the efficiency of extraction of platinum from platinum ores with mercury.[58] The effect is attributed to the lowering of the surface tension of the mercury by the sodium, which thus increases the tendency of the mercury to wet the precious metals in the ores.[12] This lowering of surface tension also underlies a suggestion that alloys of tin or zinc containing small amounts of sodium are advantageous in promoting thin coatings of sheet iron with tin or zinc.[12,59,60]

A zinc–sodium alloy has been proposed for use in electroplating zinc from zinc cyanide.[61]

In view of the early history of the production of sodium (see page 368) it is interesting to note that in recent years the preparation of metals such as calcium,[61a, b] zirconium,[62, 62a] titanium,[63–72c] beryllium and tantalum,[73, 74] vanadium and chromium[75] by the reduction of their compounds with sodium has been investigated, and in at least one case, namely that of titanium, apparently with considerable success. According to recent information, the preparation of titanium by the reduction of titanium tetrachloride with sodium has now been adopted on the commercial scale in England[65] and America[70] and this process will be dealt with in a later Supplement. The 'Argon grade' sodium available on the market in the U.S.A. is recommended for use in the preparation of metals such as titanium or zirconium.[76] Boron and silicon have also been produced by the reduction of their respective chlorides with sodium.[76a, b]

Many metal salts and oxides react smoothly with sodium absorbed on inert carriers. Such reactions proceed rapidly and completely at relatively low temperatures, and the metals so produced are colloidal and therefore in an extremely reactive form, which for some purposes may be very advantageous.[77] Examples of metallic compounds that have been reduced in this way include lead chloride, copper chloride, nickel chloride, silicon tetrachloride, titanium tetrachloride, zirconium tetrachloride, chloroplatinic acid, iron oxide, zinc oxide and metal soaps such as nickel oleate.[39]

A patent describes the preparation of powdered metals at low temperatures using sodium dispersed in toluene or ether.[39a]

The preparation of metallic powders by reducing a metallic compound with a sodium metal addition-compound of ethers of polyhydric alcohols such as glycol ether, has been patented.[78–78b] The sodium addition-compound is conveniently prepared by causing the ether of a polyhydric alcohol to react with metallic sodium in a subdivided state e.g. as a dispersion of sodium in an inert liquid medium. The method has been used to produce powders of iron, cobalt, chromium, manganese, molybdenum, zinc, tin and silver. Powder alloys of iron–cobalt and iron–chromium as well as other mixtures of different metal powders are prepared in a similar manner.

An interesting minor application is that of improving the effectiveness of automobile lubricating oils. A sodium 'slug' in a special fitting in the oil feed line greatly increases the useful life of the oil, perhaps by removing, or preventing, formation of the deleterious oxidation products which are mainly responsible for the deterioration of lubricating oils.[89] Leaks in pipes are studied by watching the movement of a slug of sodium, ^{24}Na.[90]

Sodium finds many other minor uses in the purification of gases,[79,80] the manufacture of photoelectric cells[81-85] and in sodium vapour lamps.[86] A liquid sodium pump for removal of oxidizing gases from inert atmospheres has been described.[86a] A 25% sodium-lead alloy (Hydrone) is used to generate hydrogen,[12] and a floating marine flare containing metallic sodium and light hydrocarbon has been patented.[87] Small quantities of sodium are employed in the manufacture of sodium azide which is used to make primers for percussion caps.[88]

SECTION XXIV

THE PHYSICAL PROPERTIES OF SODIUM

By W. H. WILSON

Structure, Atomic and Ionic Radii, Etc.

While the silvery-white surface of freshly-cut sodium tarnishes almost instantaneously in air, surfaces cut under liquid nitrogen remain bright for several hours at -196°C. even though no special precautions are taken to prevent precipitation in the liquid nitrogen of ice from the moisture of the air.[1] Sodium can be polished metallographically in the same way as can lithium (see page 31) but by using propyl alcohol instead of methyl alcohol.[2] Brilliantly lustrous dodecahedra of sodium have been obtained by the slow evaporation of a liquid ammonia solution of the metal.[3]

Single crystals of sodium may be prepared by allowing the liquid metal to cool very slowly in oiled tubes.[4-6] Basically similar techniques for doing this have been devised independently by Andrade and Tsien[4] and by Quimby and Siegel.[5] The former workers contained the sodium in a tube 13 cm. long and 2 mm. in diameter, and this was lowered at a rate of 12 cm. per hour from a jacket maintained at 100°C. Quimby and Siegel lowered the containing tube from a heated zone at a rate of 5 cm. per hour and obtained crystals with a diameter of 4·7 mm. which were single over their entire length of 10 cm. The crystals showed no tendency to grow in any preferred orientation.

Sodium crystallizes as a body-centred cube, the most precise value for the lattice constant being 4·2820 ± 0·0005 A. at 20°C.[7] This corresponds to an atomic radius of 1·85 A. Other values of 4·27 A.,[8] 4·29 A.[9] and 4·30 A.[10] have been reported for the lattice constant at ordinary temperatures. The body-centred cubic lattice still holds at 90° to 100°K. where the lattice constant is 4·24 A.[11,12]

There is evidence of a transformation to a face-centred cubic structure in sodium that has been cold worked at liquid hydrogen temperature and then *X*-rayed at - 195°C.[13] This strain-produced modification may be likened to that found in cold worked lithium at liquid nitrogen temperatures (see page 32). The lattice constant of the face-centred cubic form is 5·339 A. at -195°C., and the densities of the two forms are almost identical.[14] More recently, Barrett[15] has sought and found in sodium at very low temperatures a spontaneous martensitic transformation analogous to the spontaneous transformation to a hexagonal close-packed structure found previously in lithium at low temperatures (see page 32). Specimens of sodium were cooled to various low temperatures and then examined metallographically near room temperature: martensitic transformations were detected by the scars left on the specimens as a result of the plastic flow that occurs. Large unrestrained grains of sodium (99·94% pure), free from oxide, were found to undergo a partial martensitic transformation when cooled below 36·2 ± 2°K. Smaller grains with unoxidized surfaces usually began to transform at about 31°K., whereas those with oxidized surfaces transformed at rather lower temperatures. On cooling to 25° to 30°K., the amount of metal transforming in oxide-free, large-grained areas was of the order of 0·1%; this amount increased to about 1 to 10% on further cooling to 1·2°K. Barrett[15] has pointed out the important bearing of these findings on all past determinations of the physical properties of sodium at low temperatures. Specimens cast in small-diameter capillaries, where strain from differential contraction may be marked, will probably not show the same transformation temperatures as more massive samples. Specimens cast on copper wires or baffles might have intermediate transformation temperatures. Oxide films and oil films may also have an effect. If much plastic flow has occurred, a large hysteresis between cooling and heating experiments may be expected. In view of the unknown and varying amounts of transformation involved in previous determinations of electrical and thermal conductivity, thermoelectric effect, and specific heat, it is considered that they provide unreliable tests of physical theories of these properties in the low-temperature range.[15]

Preferential crystal orientation giving rise to a fibrous structure has been observed in threads of sodium after thermal and mechanical treatment, and the direction of the crystal orientation has been investigated.[8,16]

Glide occurs in single crystals of sodium when they are extended slightly.[4,17] The glide planes are visible as regular and parallel surface markings, and hardening occurs round them. With increase of temperature from −185° to 20°C. the glide plane changes successively from (112) to (110) to (123), but the direction of glide is in all cases [111].[17] At the lower temperatures the spacing of the glide planes is much closer than at room temperature. For a rate of flow of about 1% per minute, the critical shear stress is 7·1 g./mm.^{2} at −185°C., 5·3 at −82°C. and 4·9 at 20°C.[17]

A strong hysteresis has been found in the *X*-ray reflecting power of single sodium crystals when subjected to a cycle of heating and cooling, but this vanished when the crystals were chilled with liquid air.[18] The diffuse scattering of *X*-rays by sodium crystals has been the subject of both experimental and theoretical study.[19–23] Detailed evaluations of the surfaces of isodiffusion of sodium[19–21] are in close agreement with the experimental investigations of the diffuse scattering of *X*-rays by single crystals.[22,23]

The rate of crystallization of sodium on cooling the liquid below the melting point has been studied[24,25] and the effect of slight oxide contamination investigated.[24] Highly oxide-free sodium may be cooled 3·5° below the melting point before crystallization starts: for oxidized sodium the figure is never more than 2·5°.[24] In a study of the crystallization velocity of sodium agitated under xylene, it is reported that at temperatures below 98° dendritic crystals were obtained and at higher temperatures cylindrical crystals resulted.[25]

The structure of liquid sodium has been widely studied[26–30a] and several theoretical treatments and reviews have appeared.[31–38b] The liquid tends to retain a structure not dissimilar to that of the solid. Fig. 1 shows the radial distribution of atoms about any one atom in the liquid at 100°C. and at 400°C.:[29] the average density curves are included as dotted lines.

At the higher temperature the increased thermal agitation of the atoms has a smearing-out effect on the distribution curve. The first peak in the radial distribution curve occurs at about 3·83 A. for 100° and at about 3·90 A. for 400°C. These distances between atoms compare with a spacing of 3·7 A. in solid sodium at room temperature. In the solid, each atom has 8 nearest neighbours at this distance; zt greater distances there are then 6 further neighbours at 4·3 A., 12 at 6·1 A., 24 at 7·1 A. and 8 at 7·4 A. The second maximum in the radial distribution curve of the liquid is at about 7·0 A. for 100°C. and at 7·2 A. for 400°C. Earlier investigations gave values of 40·0 A.[28] (later corrected to 3·86 A.[29]) and 4·04 A.[26] for the first peak in sodium a little above its melting point. The radial distribution curves of Fig. 1 were obtained from the *X*-ray diffraction pattern by Fourier analysis utilizing the

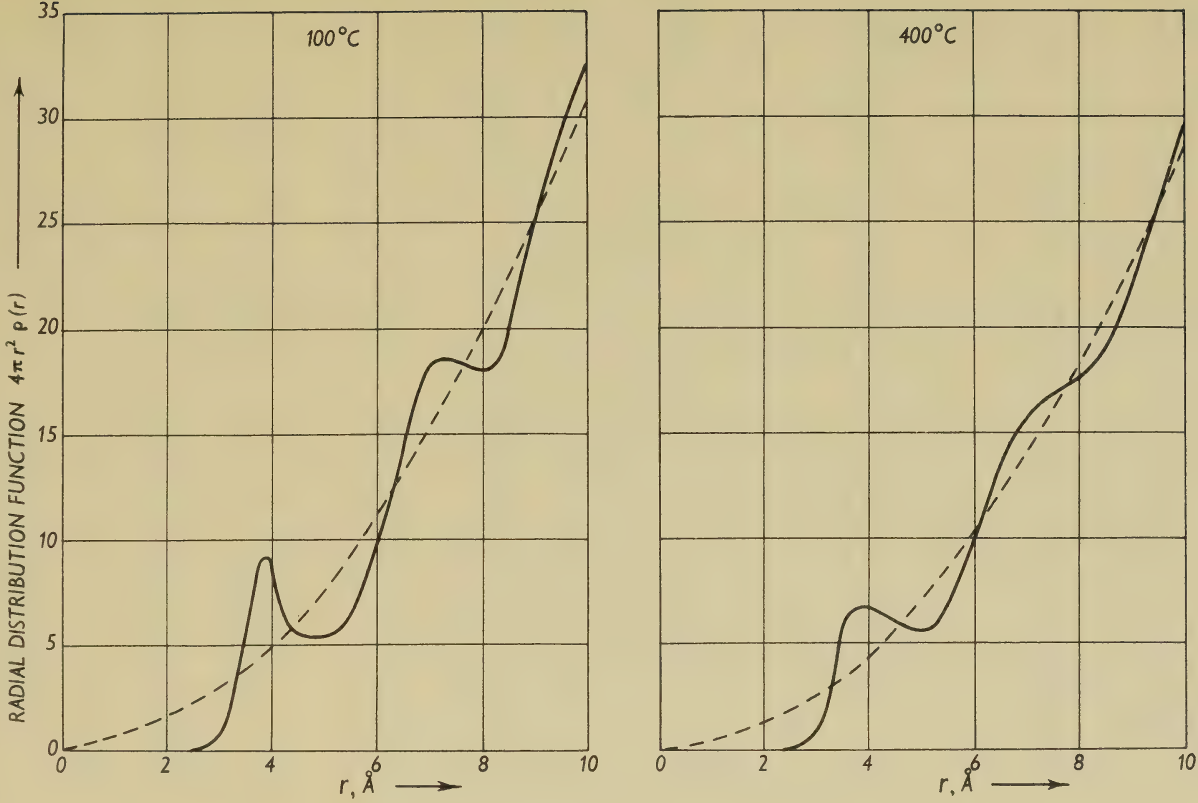

FIG. 1. RADIAL DENSITY DISTRIBUTION OF ATOMS ABOUT ANY ONE ATOM IN LIQUID SODIUM AT 100° AND 400°C.

Refs. p. 411

Zernike and Prins[39] formula. Wall[34] developed a different distribution function for liquid sodium and fitted it to the same experimental data as used for Fig. 1. He found that at 100°C. each sodium atom has an average of 9·28 nearest neighbours at a distance of 3·79 A. corresponding to a free space of radius 0·6 A. At 400°C. there are 8·95 nearest neighbours lying at 3·80 A. and the free space radius is 0·77 A. On fusion there is thus an increase in the co-ordination number from its value of 8 in the solid. From the atomic distribution function, Wall has calculated the latent heats of fusion and vaporization of the metal with fair success.

Sodium provides a close approximation to the free electron model of the metallic state. This model, picturing a metal as a sea of free electrons in which are immersed a series of positive ions, has been used as a basis for theoretical calculations of many physical properties of sodium. In general, there is reasonably close agreement between the theoretical and experimental values.

Quantum mechanical treatments of the energy levels and of the bonding and cohesion in metallic sodium have been made by a number of authors.[40-60] In an early treatment, Slater[41] applied the London–Heitler method of homopolar binding to the calculation of the cohesive forces in sodium, but the approximation method developed by Wigner and Seitz,[43,44] and first applied to the case of sodium, has proved more successful in dealing with binding in the alkali metals. The Wigner–Seitz method uses the free electron picture and treats separately the valence electrons and the cores, it being assumed that the forms of the closed shells are not altered by metallic binding. If, in a monatomic body-centred cubic structure such as that of sodium, planes are drawn to bisect the lines joining an atom to each of its nearest and next nearest neighbours, the result is a set of space-filling 'atomic polyhedra' of 's-polyhedra', each taking the form of a truncated octahedron (Fig. 2). Since these have a fairly high symmetry, Wigner and Seitz make the approximation that they can be replaced by spheres of the same volume. A number of other simplifying assumptions are made concerning the occupation and interaction of these polyhedra, and wave functions are calculated for the valence electrons in their lowest state. The energy associated with the wave functions is used to obtain the cohesive or binding energy of the crystal.

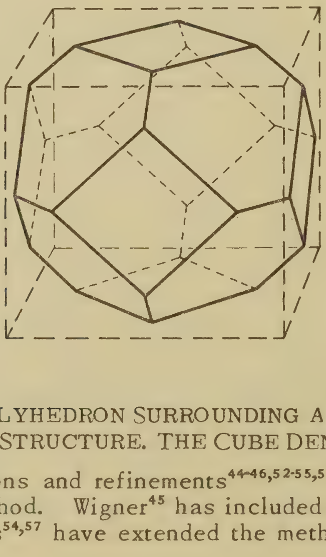

FIG. 2. ATOMIC POLYHEDRON SURROUNDING A SODIUM ATOM IN A BODY-CENTRED CUBIC STRUCTURE. THE CUBE DENOTES THE UNIT CELL.

A number of extensions and refinements[44-46,52-55,57] have been made to the original Wigner–Seitz method. Wigner[45] has included correlation forces, while Slater[46] and later workers[54,57] have extended the method to the computation of the excited bands of electrons in sodium. Kuhn and Van Vleck[55] have developed a method which, within the limits of spherical cell approximation, permits the evaluation of the cohesive energy and lattice constant of sodium without the computation of a central field for the atom. More recently Löwdin[55a] has calculated the cohesive energy using a linear combination of atomic orbitals and by introducing what he terms combined atomic orbitals. Although good agreement with experiment is obtained for the lattice parameter, reasons have been advanced for preferring the Wigner-Seitz approach.[57b] Values of the lattice constant and the cohesive or binding energy calculated by a number of authors are compared with the experimental values in Table I.

TABLE I.- CALCULATED AND EXPERIMENTAL VALUES FOR THE LATTICE CONSTANT AND COHESIVE ENERGY OF SODIUM

	Calculated							Experimental*
	Ref. (43)	Ref. (58)	Ref. (50)	Ref. (52)	Ref. (55)	Ref. (55a)	Ref. (57b)	
Lattice constant, A. units	4·2	4·51	4·35	4·53	4·14	4·26	4·27	4·23
Cohesive energy, kg.-cal./g.-atom	25·6	24·5	21·0	23	25·9	24·7	26·5	26

* The experimental values are extrapolated to 0°K.

In view of the approximate methods that have to be employed in the calculations, no great reliance can be placed on the exact numerical values. It is seen, however, that the theory of binding does give cohesive forces of the right order of magnitude. Since in the Wigner-Seitz method the assumption is made that the elementary cell can be replaced by a sphere, the energy becomes a function of atomic volume only and not of the crystal structure. It is not possible, therefore, in the present state of the theory to discuss allotropic transformations and to calculate, for example, the energy difference between the body-centred and face-centred forms of sodium.[60] More detailed reviews of the various quantum mechanical methods are available.[58-60]

Pauling,[61] in formulating a set of ionic radii based on only five experimental interionic distances, namely those in NaF, KCl, RbBr, CsI and Li_2O, gave 0·95 A. for the radius of the Na^+ ion (Li^+, 0·60 A.; K^+, 1·33 A.; Rb^+, 1·48 A.; Cs^+, 1·69 A.). Goldschmidt[62] in an earlier treatment gave 0·98 A. for Na^+. These and other earlier treatments have been reviewed.[61,63]

Density and Thermal Expansion

The density of solid sodium has been reported as 0·9690 at 18°C.[64] and as 0·9735 at 20°C.[65] *X*-Ray measurements[7] lead to 0·9660 at 20°C. A figure of 0·9723 was previously given (Mellor,II,452) as the best representative value at 20°C. In view of the variation among these figures there seems little justification at present in giving the density at room temperature to more than two significant figures. Low temperature measurements have given the density as $1{\cdot}01_5$ at 77°K. and $1{\cdot}01_0$ at 4·2°K.[66] At 100°K. the density calculated from *X*-ray data is 0·996: the value at 0°K. has been given as 1·01.[12]

Rinck[67,68] made measurements of the density of liquid sodium between approximately 400° and 600°C. which fitted the equation:-

$$d_4^t = 0{\cdot}9385 - 0{\cdot}000260(t - 96{\cdot}5).$$

This equation agrees closely with older density values at both the melting point[69] and the boiling point (Mellor,II,453), and it was used by Rinck over the entire liquid range of sodium. More recent measurements[70] over the range 254° to 860°C. have led to the equation:-

$$d = (0{\cdot}9378 \pm 0{\cdot}0086) - (0{\cdot}000268 \pm 0{\cdot}000018)(t - 97{\cdot}5),$$

which is in close agreement with that of Rinck. Measurements by Novikov *et al.*[70a] from the melting point to 720°C. gave a good fit to a straight line, densities at 100°C. and 700°C. being 0·928 and 0·795 respectively. Other recent density values for liquid sodium are:-[71,72]

Temp., °C.	100	250	400	550	700
g./cm.^{3}	0·928	0·891	0·854	0·817	0·780

These data have been represented by the equations:-

$$d(\text{g./cm.}^3) = 0{\cdot}957 - 2{\cdot}7 \times 10^{-4}T \ (T \text{ in } ^\circ\text{C.})^{73}$$

$$\text{and } d(\text{lb./ft.}^3) = 63{\cdot}75 - 8{\cdot}766 \times 10^{-3}T + 9{\cdot}091 \times 10^{-8}T^{-2} \ (T \text{ in } ^\circ\text{F.}).^{74}$$

They give slightly lower densities than the first two equations quoted above. Density values at 5°F. intervals between 208°F. and 1500°F. have been listed[74] using the last equation. Rounded representative values for the density of sodium between 20° and 800° are given in Table II.

TABLE II.- DENSITY OF SODIUM

Temp., °C.	20	100	200	300	400	500	600	700	800
d	0·97	0·94	0·91	0·88	0·85	0·83	0·80	0·78	0·75

The increase in volume on fusion has been reported as 2·53%[65] and as 2·17%[64] or 0·0222 c.c. per gram.

The linear thermal expansion of single crystal specimens of sodium has been measured at 10° intervals between 80° and 290°K.[75] Some of the values are shown in Table III.

TABLE III.- THERMAL EXPANSION OF CRYSTALLINE SODIUM

T, °K.	$(l_T - l_{273}) \times 100/l_{273}$
80	−1·155
100	−1·071
120	−0·970
140	−0·860
160	−0·742
180	−0·621
200	−0·493
220	−0·361
240	−0·226
260	−0·090
280	+0·047
290	+0·116

Values for the mean coefficient of linear thermal expansion of sodium over the range 0 to 95°C. for pressures from zero up to 20,000 kg./cm.^{2} are given in Table IV.[76,77]

TABLE IV.- EFFECT OF PRESSURE ON THE THERMAL EXPANSION OF SODIUM

Pressure, kg./cm.^{2}	0	2000	4000	6000	8000	10,000
α(0 to 95°C.) × 10^5	7·1	$6{\cdot}2_2$	$5{\cdot}5_3$	$4{\cdot}9_5$	$4{\cdot}5_0$	$4{\cdot}0_8$

TABLE IV continued

Pressure, kg./cm.^{2}	12,000	14,000	16,000	18,000	20,000
α(0 to 95°C.) × 10^5	$3{\cdot}7_0$	$3{\cdot}3_7$	$3{\cdot}3_0$	$2{\cdot}6_5$	$2{\cdot}3_3$

Fröhlich[51] has discussed the thermal expansion of sodium from a quantum mechanical standpoint. A later treatment by Balamuth[78] has given closer agreement with experiment.

Mechanical and Elastic Properties

Bridgman[76,77,79-85] has made extensive investigations of the effect of pressure on the volume of sodium. Table V, based on his more recent work, shows the relative volumes at room temperature for pressures up to 100,000 kg./cm.^{2}.[82,83]

TABLE V. - EFFECT OF PRESSURE ON THE VOLUME OF SODIUM AT ROOM TEMPERATURE

Pressure, kg./cm.^{2}	Relative Volume	Pressure, kg./cm.^{2}	Relative Volume
0	1·000	40,000	0·737
2,500	0·967	50,000	0·708
5,000	0·938	60,000	0·683
10,000	0·888	70,000	0·661
15,000	0·849	80,000	0·641
20,000	0·816	90,000	0·623
25,000	0·789	100,000	0·606
30,000	0·765		

The compressions of the five alkali metals are compared in Supplement 3. Equations[79] for the volume change at 30°C. and 75°C. with pressures up to 12,000kg./cm.^{2} require some revision in the light of later findings.[76,86] Another recent study[66] of the compression at low temperatures has given the figures in Table VI for the relative volumes of sodium at 4·2°K.

TABLE VI. - EFFECT OF PRESSURE ON THE VOLUME OF SODIUM AT 4·2°K.

Pressure, atmospheres	Relative Volume	Pressure, atmospheres	Relative Volume
0	1·000	3,000	0·962
500	0·993	4,000	0·951
1000	0·987	6,000	0·930
1500	0·980	8,000	0·912
2000	0·974	10,000	0·895

Bridgman[76] found that the compressibility of sodium increased with decrease of pressure to an extrapolated value of 17×10^{-12} cm.^{2}/dyne at zero pressure and room temperature. Earlier[79] he gave the initial compressibility at 30°C. as $15{\cdot}62 \times 10^{-12}$ cm.^{2}/dyne. Richards and co-workers[87] obtained a value of $15{\cdot}6 \times 10^{-12}$ cm.^{2}/dyne for the average compressibility of sodium at 25°C. for pressures between 10^8 and 5×10^8 dynes/cm.^{2} This is the same as the value given previously for 20°C. (Mellor,II,455). The same value has also been given for the compressibility at zero pressure and 80°K.[88] Other recent values[66] of the initial compressibility at low temperatures are $15{\cdot}4 \times 10^{-12}$ cm.^{2}/dyne at 77°K. and $13{\cdot}7 \times 10^{-12}$ cm.^{2}/dyne at 4·2°K. It should be pointed out that some earlier workers, including Richards, in giving pressures and compressibilities used the term 'megabar' to denote a pressure of 10^6 dynes/cm.^{2}: this usage is quoted in Mellor's original treatise. The term 'bar' is currently used to denote a pressure of 10^6 dynes/cm.^{2} To avoid any confusion, all values given in bars by the original authors have here been converted to dynes/cm.^{2}

Based on a value[89,89a] of 2526m./sec. for the velocity of ultrasonic waves in liquid sodium at its melting point (97·6°C.), the adiabatic compressibility has been found to vary from $16{\cdot}85 \times 10^{-12}$cm.^{2}/dyne at the melting point to $19{\cdot}02 \times 10^{-12}$cm.^{2}/dyne at 272°C.; the temperature coefficient changed only slightly from $0{\cdot}012 \times 10^{-12}$cm.^{2}/dyne per degree C. at 97·6°C. to $0{\cdot}013 \times 10^{-12}$ at 272°C.[89a] Corresponding values for the isothermal compressibility are $19{\cdot}11 \times 10^{-12}$cm.^{2}/dyne at the melting point and $22{\cdot}19 \times 10^{-12}$cm.^{2}/dyne at 272°C.[89a] Another worker[90] gives $17{\cdot}7 \times 10^{-12}$cm.^{2}/dyne for the adiabatic compressibility of liquid sodium at its melting point, and $21{\cdot}0 \times 10^{-12}$cm.^{2}/dyne for the isothermal compressibility at the same temperature.

Theoretical treatments of the compressibility of sodium have been given by several authors.[43,50,51,53,55,91-94]

Using a test specimen of length 30 mm. and diameter 3 mm., the tensile strength of sodium at +17, −196 and −253°C. has been determined as 1·4, 1·9 and 4 kg./sq.mm. respectively.[95] The elongation at rupture for these three temperatures was 19, 18 and 60% respectively. Sodium thus becomes distinctly more plastic at low temperatures. For polycrystalline sodium rods,[96] the extension modulus at 20°C. is about 3×10^{10} dynes/cm., while the tension or rigidity modulus at this temperature is $9{\cdot}6 \times 10^9$ dynes/cm. Measurements by Dawton[96] on single sodium crystals gave values varying between 31×10^9 and 14×10^9 for the extension modulus at 20°C., and between 9×10^9 and 35×10^9 for the torsion modulus, depending on the orientation of the crystal. Extrapolating to absolute zero from measurements in the range −183 to 90°C., Young's modulus was given as 56×10^9 dynes/cm. in the direction of the [100] axis: the torsion modulus was 15×10^9 dynes/cm. in the [110] direction and 59×10^9 dynes/cm. in the [100] direction.[96]

For cubic crystals such as sodium there are only three independent values for the elastic 'moduli' or compliances (S_{11}, S_{12} and S_{44}), and for the elastic constants (C_{11}, C_{12} and C_{44}). Values of the adiabatic elastic constants between 80° and 210°K. are given in Table VII.[5] Isothermal constants derived from them are given in Table VIII. The isothermal values of S_{44} and C_{44} are the same as the respective adiabatic values. The estimated uncertainty in the absolute values in Tables VII and VIII is 2–3%.

TABLE VII. - ADIABATIC ELASTIC CONSTANTS OF SODIUM

T°K.	cm.^{2}/dyne × 10^{-11}			dynes/cm.^{2} × 10^{11}		
	S_{11}	$-S_{12}$	S_{44}	C_{11}	C_{12}	C_{44}
80	4·826	2·087	1·685	0·608	0·463	0·593

210	5·361	2·313	0·541	0·410

from the quantum mechanical calculations of Fuchs[97,98] are $C_{11} = 0{\cdot}97 \times 10^{11}$ dynes/cm.², $C_{12} = 0{\cdot}83 \times 10^{11}$ dynes/cm.² and $C_{44} = 0{\cdot}58 \times 10^{11}$ dynes/cm.[22] Other values of the elastic constants have been calculated by Bulashevich[99] and by Totani.[99a]

The relation between the diffuse reflection of X-rays by a set of planes in a crystal and the normal (Bragg) reflection is determined by the elastic constants of the crystal. This has been studied and discussed for the case of sodium.[19-23]

Sodium shows an unusually great increase in its shearing strength with increase of pressure, and with decreasing pressure there is an unusually large hysteresis.[100] At a hydrostatic pressure of 50,000 kg./cm.² the shearing stress for plastic flow is 5200 kg./cm.².[100]

No recent work appears to have been done on the hardness of sodium.

Surface Properties

Determinations of the surface tension of sodium have been carried out by a number of methods, the majority of them leading to a value of about 200 dynes cm.$^{-1}$ for the surface tension at the melting point. Measurements on a sessile drop of sodium in a vacuum gave 206·4 dynes cm.$^{-1}$ at 100°C. and 199·5 dynes cm.$^{-1}$ at 250°C., the temperature coefficient being -0·046 dynes cm.$^{-1}$ degree^{-1}.[101] Capillary-rise in glass has given 110 to 125 dynes cm.$^{-1}$ in the lower temperature range,[72] while the maximum bubble pressure method has given 190·8 dynes cm.$^{-1}$ at the melting point with a temperature coefficient of -0·1 dynes cm.$^{-1}$ degree^{-1} from the melting point up to 450°C.[102-104] By the use of a vertical plate technique,[73] γ = 186 dynes cm.$^{-1}$ was found at 180°C.; the temperature coefficient was -0·1 dynes cm.$^{-1}$ degree^{-1} which by extrapolation gives γ = 195 dynes cm.$^{-1}$ at the melting point of sodium. Measurements by a drop-volume method[105] over the temperature range 110-220° have also given a temperature coefficient of -0·1 dynes cm.$^{-1}$ degree^{-1}, and extrapolation to the melting point gave γ = 202 dynes cm.$^{-1}$ A theoretical treatment[106] has given -0·09 dynes cm.$^{-1}$ degree^{-1} for the temperature coefficient of the surface tension.

Calculations[107-114] of the surface energy of sodium using electronic theories have given values both considerably greater and considerably smaller than those obtained experimentally. Thus, values calculated by the use of the free-electron model have ranged from about one quarter[111] to three times[109] the mean observed value. The value in closest agreement with experiment is γ = 190 dynes cm.$^{-1}$ calculated by Stratton.[113]

A film of sodium oxide on the surface of sodium metal increases the apparent surface tension,[73,102,103,115] but if oxide is present below its solubility limit it may have the opposite effect.[73,115] The interfacial tension between liquid sodium and sodium crystals has been given as 2 dynes cm.$^{-1}$ for samples very free from oxide;[24] slight oxide contamination can reduce the figure by a factor of four.

From the surface tension of metallic sodium the parachor is 92. Values of the parachor calculated from surface tension data for fused salts[116] and for salts in solution[117] are 80 and 90 respectively.

Numerous metals are said to show a critical temperature of wetting by sodium.[73,118] Above this critical temperature, wetting by sodium is a ready process; below it, wetting occurs with difficulty if at all. The wetting temperature of zinc lies between 128° and 180°, and it has been reported that copper and molybdenum are not wetted at these temperatures.[73] Miller *et al.*[119] determined the wetting temperature of nickel as 355 ± 5°C., and that of low-carbon steel as 370 ± 5°C. Other workers,[118,120] however, have reported that clean surfaces of molybdenum and low-carbon steel are wetted by sodium at its melting point, and that the wetting temperatures for clean surfaces of nickel, stainless steel 347 (18% Cr, 10% Ni, 1% Nb), and glass are 230-260°, 138-168°, 306-333°C. respectively. Coatings of oxide or grease have a considerable effect on the wetting temperature,[118,120] and such coatings are, no doubt, responsible for the variable results that have been recorded. In the last mentioned investigations, the wetting temperatures of oxide-coated molybdenum and low-carbon steel, for example, were raised to 267° and 292-426°C. respectively.[118,120] Sodium oxides are not wetted by liquid sodium.[73] The wetting of metals by sodium-potassium alloys has also been studied.[121]

High Surface Sodium, Sodium Dispersions and Colloidal Sodium

Liquid sodium spreads over many inert substances of large surface area, e.g., salt, carbon, alumina and metal powders, to give a covering film which may approach atomic dimensions in thickness.[122] Quite high percentages of sodium may be adsorbed in this way without the solids losing their free flowing characteristics. Sodium chloride, depending on its crystal size, will carry 2-10% of sodium; sodium carbonate will carry 10% of sodium; alumina, 20-25% of sodium; and activated or colloidal carbons, over 30% of sodium. At higher sodium concentrations the mixtures become pasty. Provided that the carrier is temperature-stable, the free flowing characteristics can be maintained up to the boiling point of sodium. Certain substances such as aniline, colloidal carbon and colloidal metals are reported to facilitate the spreading of sodium over inert materials. A number of high-surface sodium systems are described in Table IX.[122]

Dispersions of sodium may be produced in many inert liquids such as toluene, xylene, heptane and *n*-butyl ether, which have boiling points above the melting point of sodium, by heating the mixture of sodium and inert liquid to between 100 and 110°C. and then applying vigorous mechanical agitation. Several laboratory and plant scale dispersion units have been described.[123] Sodium particles with diameters ranging from 20 microns to less than one micron may be obtained depending on the method of preparation, and the dispersions may contain up to 50% of sodium. In general, the dispersions have nearly the same fluidity as the dispersing medium, and properly formulated dispersions may be used above or below the melting point of sodium without coalescence of the particles. Certain additives assist in the preparation of sodium dispersions. Some metal powders, for example, serve to break down the sodium particle size but do not stabilize the dispersions. Other materials - such as the aluminium salts of long chain fatty acids - as well as assisting in particle size breakdown, give dispersions which do not ordinarily coalesce in three months.[123] The patent literature contains numerous references to other dispersing and stabilizing agents for use in the preparation of

TABLE IX. - HIGH SURFACE SODIUM SYSTEMS

Solid Carrier	Optimum Dispersing Temp., °C.	% Sodium	Appearance
Sodium Chloride 130–420 μ	150	2–10	Grey to black salt
Sodium Carbonate 50–150 μ	150	10	Grey to black powder
Activated Alumina	140–160	20–25	Black or mottled white granules
Activated Carbon (coconut)	120	35+	Silver to black pyrophoric powder
Colloidal Carbon	170	>30	Black pyrophoric powder
Iron Powder 150 μ	150–200	5	Grey powder
White Sand 420–840 μ	150–165	5	Grey surfaced sand
Zirconium Oxide <50 μ	250	10	Dark grey powder

sodium dispersions.

Colloidal solutions of sodium have been prepared by condensation methods.[124–127] Sodium vapour may be passed into the cooled dispersion liquid, or the mixed vapours of sodium and the dispersion medium may be condensed on a cooled surface. Reduced pressures are usually used in both cases. Tomashevskii,[125] using such methods, prepared sodium sols in ether which were stable for a month; they showed an absorption spectrum from 6238 to 4696 A. with the violet end polarized. Sodium sols in xylene were stable for twelve to twenty hours, while sols in benzene had a dirty-green colour and were stable for three days. Lauer[128] prepared ~0·3% sodium sols in ether by passing an alternating or direct current between a dipping electrode and sodium spheres under the ether. Ultrasonic waves have also been used in preparing colloidal solutions of sodium.[129,130b]

Sodium dispersions and other high-surface forms of sodium find many applications in chemical reactions (see pages 427–547).

Viscosity

Viscosity measurements for sodium, made up to 200°C.[131] using a glass Ostwald-type viscometer and at higher temperatures up to 700°C.[132] using a similar apparatus in nickel, are given in Table X. The values up to 200°C. have been represented by the equation:-

$$\eta v^{\frac{1}{3}} = 1{\cdot}089 \times 10^{-3} e^{756{\cdot}9/vT},$$

and those for the whole range from the melting point to 700°C. by:-

$$\eta v^{\frac{1}{3}} = 1{\cdot}142 \times 10^{-3} e^{739{\cdot}8/vT}$$

where v is the specific volume and T the absolute temperature. These measurements are in close agreement with others[133] carried out by an oscillating

TABLE X.- VISCOSITY OF SODIUM

Temp., °C.	Viscosity, c.g.s. units × 10^2	Temp., °C.	Viscosity, c.g.s. units × 10^2
103·7	0·686	292	0·354
121·6	0·620	371	0·308
147·0	0·548	447	0·270
167·0	0·504	506	0·240
192·7	0·460	571	0·216
250	0·388	686	0·183

sphere method from the melting point to 355°C. ($\eta = 0{\cdot}7264 \times 10^{-2}$ c.g.s. at 98°C., $0{\cdot}3015 \times 10^{-2}$ c.g.s. at 355°C.), the maximum disagreement being less than 2% at 350°C. The last mentioned results were expressed by the equation:-

$$\eta v^{1/3} = 1{\cdot}142 \times 10^{-3} e^{600{\cdot}0/vT}$$

except near the melting point where higher viscosities were obtained suggesting the persistence of a crystal structure for a few degrees above the melting point. Damping characteristics of torsional oscillations in a freely suspended crucible containing sodium were also studied by Novikov *et al.*[70a] to obtain the kinematic viscosity ($\nu = \mu$/density) between the melting point and 800°C. Interpolated values of kinematic viscosity from the graphically presented results are:-

Temp.°C.	100	150	200	300	400	500	600	700	800
ν (c.g.s. units × 10^2)	0·80	0·58	0·50	0·39	0·33	0·29	0·26	0·23	0·21
η (c.g.s. units × 10^2)	0·74	0·53	0·45	0·35	0·28	0·24	0·21	0·18	0·16

The last line shows viscosities obtained by combining the kinematic viscosities with the same workers' density determinations. There is close agreement with the previous measurements.[132,133] Other earlier and less precise measurements made in the vicinity of the melting point gave values several per cent. higher than those quoted above.[134,135] Experimental values for the viscosity of sodium have been related to the binding energy of the molecules of the liquid and to the entropy of bond formation.[136]

Diffusion

The coefficient of self-diffusion for solid sodium increases from $9{\cdot}22 \times 10^{-10} \pm 2{\cdot}47 \times 10^{-10}$ cm.^{2}/sec. at 0°C. to $1{\cdot}43 \times 10^{-7} \pm 0{\cdot}02 \times 10^{-7}$ cm.^{2}/sec. at 95°C., and at one atmosphere pressure the temperature variation may be expressed by the equation:-[1]

$$D_{\text{solid}}\ (\text{cm.}^2/\text{sec.}) = 0{\cdot}242 e^{-10{,}450/RT}$$

Hydrostatic pressure decreases the rate of self-diffusion; at 8000 atmospheres the equation becomes:-[137]

$$D_{(8000\ \text{atm.})}\ (\text{cm.}^2/\text{sec.}) = 0{\cdot}176 e^{-12{,}060/RT}.$$

When both are considered as a function of pressure, the free energy of activation is a linear function of the melting point.[137] Similarly the enthalpy of activation is related to the latent heat of fusion by the equation, $H = 16{\cdot}5\ L_m$. There is an increase in the rate of self-diffusion at the melting point; at one atmosphere pressure, $D_{\text{solid}} = 2{\cdot}16 \times 10^{-7}$ cm.^{2}/sec. at 97·83°C. and $D_{\text{liquid}} = 4{\cdot}19 \times 10^{-5}$ cm.^{2}/sec. at 98·0°C.[138] The diffusion coefficient for the liquid between the melting point and 226°C. may be represented by the equation:-[139]

$$D_{\text{liq.}}\,(\text{cm.}^2/\text{sec.}) = 1{\cdot}10 \times 10^{-3} e^{-2430/RT}$$

Self-diffusion in sodium has been discussed in relation to its nuclear magnetic resonance,[140,141b] and from nuclear resonance data the coefficient of self-diffusion at –56°C. has been estimated[141] as $1{\cdot}3 \times 10^{-11}$ The activation energy of self-diffusion has been estimated as $9{\cdot}5 \pm 1{\cdot}5$ kg.-cal./g.atom from nuclear magnetic resonance data[140] and as $9{\cdot}1 \pm 0{\cdot}1$ kg.-cal./g.atom from the anomalous rise of electrical resistance that starts well below the melting point.[141c,d] The mechanism of self-diffusion in alkali metals has been discussed by Paneth.[142]

Diffusion of sodium vapour in nitrogen and other gases has been studied in connexion with the use of sodium in diffusion flame experiments.[143,144] Measurements were actually made at pressures of about 1 to 4 mm. of mercury, but it is usual to assume that the diffusion constant is inversely proportional to the total pressure and to give the results for a total pressure of one atmosphere. In nitrogen at one atmosphere the diffusion constant is $0{\cdot}68 \pm 0{\cdot}03$ cm.^{2}/sec. at 253·5°C.[144] and 0·91 cm.^{2}/sec. at 382°C.[143] Other diffusion constants at approximately 380°C. and one atmosphere pressure are 3·14 cm.^{2}/sec. in hydrogen, 2·17 cm.^{2}/sec. in helium, 0·88 cm.^{2}/sec. in argon and 0·23 cm.^{2}/sec. in pentane vapour.[143] Measurements have also been made in hydrogen–nitrogen, hydrogen–argon, hydrogen–pentane and nitrogen–pentane mixtures.[143] At 15°C, and a pressure of 1 mm. mercury the diffusion constant of sodium in nitrogen has been given as 20·4 cm.^{2}/sec.[145] Other measurements have been made of the diffusion of sodium atoms in flames at temperatures of about 1700–2100°K.[146,147]

When alkali halide crystals are heated in an alkali metal vapour, or when crystals with alkali metal imbedded in the side are heated to 400–800°C., the crystals assume a deep colour and acquire a stoicheiometric excess of alkali metal. The colour of these 'Farbzentren' is characteristic of the crystal and not of the alkali metal. Diffusion of sodium atoms into sodium chloride crystals under such conditions has been studied.[148-150] With the aid of the ultramicroscope it has been shown that the diffusion follows cracks in the crystal lattice.[150]

Ransley and Neufeld[151] have studied the diffusion of sodium in aluminium: approximate values for the diffusion coefficient are 2×10^{-9} cm.^{2}/sec. at 550°C., 1×10^{-8} cm.^{2}/sec. at 600°C., and 7×10^{-8} cm.^{2}/sec. at 650°C. The coefficient of diffusion of sodium in mercury at 8 to 15°C., as calculated from atomic radius and viscosity data with the aid of the Stokes–Einstein equation, is 0·59 cm.^{2} per 24 hours.[152] This figure is in reasonable agreement with the older experimental value of 0·64 cm.^{2} per 24 hours (Mellor, II, 456). Measurements of the diffusion of sodium in mercury at 22°C. have given $D = 0{\cdot}80 \times 10^{-5} \pm 0{\cdot}04 \times 10^{-5}$ cm.^{2}/sec.(≡ 0·69 cm.^{2} per 24 hours)[152a]

Melting Point and Heat of Fusion

The triple point of pure sodium is $97{\cdot}82 \pm 0{\cdot}02$°C.[153,153a] An earlier measurement by the same workers gave $97{\cdot}80 \pm 0{\cdot}03$°C., and the melting point of the pure metal at a pressure of one atmosphere was calculated to be 0·01°C. higher than the triple point.[154] Other measurements of the melting point have given values only slightly different from this, viz. $97{\cdot}91 \pm 0{\cdot}06$,[138] $97{\cdot}8 \pm 0{\cdot}1$,[155] $97{\cdot}7 \pm 0{\cdot}1$,[64] 97·7[156] and 97·6°C.[157] The melting point increases with increase of pressure, and a value of 350°C. has been estimated for the limiting melting point at high pressures.[158] Melting point–pressure curves for the alkali metals are compared in Supplement 3, the sodium curve being based on previously quoted determinations (Mellor, II, 456).

A recent calorimetric determination has given $113{\cdot}2 \pm 0{\cdot}4$ joule/g. (equivalent to 27·05 g.-cal./g.) for the latent heat of fusion of sodium.[154] This agrees well with the values of 27·1 and 27·2 g.-cal./g. reported previously (Mellor,II,457). Kelley[159] has discussed the calculation of the heat of fusion of sodium from freezing point data for binary sodium systems. A rounded average value of 640 g.-cal./g. atom (≡ 27·8 g.-cal./g.) was obtained using the results of several workers for the systems Na–Au, Na–Hg and Na–Tl. A number of other binary systems, including Na–Al, Na–Ag, Na–Bi, Na–Ca Na–Li, Na–Mg, Na–Pb, Na–Sb, Na–Sn and Na–Zn, are considered to be unsuitable for calculating the heat of fusion of sodium owing to the existence of either a eutectic or two liquid phases near 100% sodium.

Theoretical calculations of the heat of fusion of sodium have appeared,[34,35] and relationships between the heat of fusion, the variation of melting point with pressure, and the volume change on fusion have been discussed.[158,160–162a] A value of 27·3 g.-cal./g. was obtained for the heat of fusion from a relationship between the parachor and the heat of fusion.[163]

Vapour Pressure, Boiling Point and Degree of Association

A number of independent measurements of the vapour pressure of sodium have been made at temperatures below its boiling point. These have led to the following equations, all of which give closely concordant values; p is in mm. of mercury and T in °K.

Temperature Range °C.	Vapour Pressure Equation	Reference
473–565	$\log_{10} p = -5780/T + 11{\cdot}435 - 1{\cdot}178 \log T$	164
182–597	$\log_{10} p = -5922/T + 12{\cdot}9605 - 1{\cdot}6184 \log T$	165
220–300	$\log_{10} p = -5573{\cdot}3/T + 9{\cdot}7255 - 0{\cdot}6794 \log T$	156
341–498	$\log_{10} p = -5773/T + 12{\cdot}439 - 1{\cdot}52 \log T$	155
341–498	$\log_{10} p = -5720/T + 11{\cdot}396 - 1{\cdot}178 \log T$	166, 155
665–768	$\log_{10} p = -5400/T + 7{\cdot}5510$	167
263–396·5	$\log_{10} p = -5400/T + 7{\cdot}551$	168

Measurements of the magnetic rotation of the plane of polarization of light by sodium vapour between 509° and 695°K.[169] have led to the equation $\log_{10} p$ (mm.) $= -5690/T + 11{\cdot}333 - 1{\cdot}178 \log T$ for the vapour pressure.[170] Using specific heat data together with the vapour pressure of sodium at one temperature, Millar[171] represented the vapour pressure of liquid sodium by the equation: $\log_{10} p$ (mm.) $= -5135/T + 11{\cdot}071 - 1{\cdot}20 \log T$; and that for solid sodium by:-

$$\log_{10} p \text{ (mm.)} = -7091{\cdot}9/T - 4{\cdot}6050 + 15{\cdot}0560 \log T - 2{\cdot}7136 (\log T)^2.$$

Rowe[172] in 1927 reviewed early work on the vapour pressure of sodium; he gave 4×10^{-13} mm. as the most probable vapour pressure of sodium at 0°C. In the same year, Rodebush[173] fitted the results of several investigators[156,164,165] to the equation $\log_{10} p$ (mm.) $= -5730/T + 11{\cdot}580 - 1{\cdot}25 \log T$. Numerous values for the vapour pressure of sodium reported prior to 1930–32 have been summarized and reviewed by Ladenburg and Thiele.[155,166] On the basis of data available up to 1934, Kelley[174] represented the total vapour pressure of liquid sodium by the equation:-

$$\log_{10} P\text{(atm.)} = -5775/T + 8{\cdot}863 - 1{\cdot}274 \log T.$$

From a graphical analysis of all the above data, Ditchburn and Gilmour[175] in 1941 gave the equation:-

$$\log_{10} p \text{ (mm.)} = -5562/T + 9{\cdot}235 - 0{\cdot}5 \log T$$

as representing the vapour pressure of sodium within ± 5% between 450° and 1200°K. and within ± 10% between 370° and 1250°K.

Recent measurements[176,177] have extended vapour pressure values up to several atmospheres. For these the boiling point of triply-distilled sodium was determined under various argon pressures, and the results over the pressure range 0·047 to 6·489 atmospheres were fitted by the equation:-[177]

$$\log P(\text{atm.}) = -5220/T + 4{\cdot}521$$

with a standard error in P of 0·9%. Temperatures at which the vapour pressure assumes rounded values calculated from this last equation and from the equation of Ditchburn and Gilmour[175] are given in Table XI.

TABLE XI. - VAPOUR PRESSURE OF SODIUM

Pressure, mm.Hg.	10^{-3}	10^{-2}	10^{-1}	1	10	10^2	760	10^3	10^4
T, °K. (Ref. 175)	511	564	630	713	821	969	1154	1180	1525
T, °K. (Ref. 177)	502	555	621	705	815	966	1154	1186	1534

The two sets of values agree within the error limit of the former equation over the range 100 to 1000 mm.; elsewhere the deviation exceeds this error limit. According to the latest investigators,[177] none of the presently available equations for sodium can be used safely to predict vapour pressure values above 5000 mm.Hg.

The recent measurements on triply-distilled sodium referred to above give the boiling point at one atmosphere as 881·3°C.[177] Extrapolation of vapour pressure data obtained at lower temperatures leads to values for the boiling point in close agreement with this. Thus, as seen from Table XI, the vapour pressure equation of Ditchburn and Gilmour,[175] which was obtained by graphical analysis of all previous vapour pressure measurements, gives a value of 881°C. for the boiling point.

At low pressures sodium vapour is largely monatomic, but with increase of pressure the percentage of molecules increases until at one atmosphere - *i.e.* at the normal boiling point - sodium molecules are present to the extent of about 15% by volume.

Values of the equilibrium constant for the dissociation of diatomic sodium vapour into atoms, computed by Gordon[178] from spectroscopic data, are given in Table XII (partial pressures in atmospheres).

Combining these figures with the vapour pressure data of several investigators, Gordon gave the following equation for the vapour pressure of monatomic sodium vapour:-

$$\log_{10} p_{\mathrm{Na}}\ (\text{mm.}) = -5702/T + 11{\cdot}3245 - 1{\cdot}174 \log T.$$

TABLE XII. - DISSOCIATION CONSTANT FOR DIATOMIC SODIUM VAPOUR

T, °K.	298·1	400	600	800	1000
Log Kp = log $(P_{\mathrm{Na}})^2/P_{\mathrm{Na}_2}$	-9·165	-5·797	-3·816	-0·823	+0·184
T, °K.	1200	1400	1600	1800	2000
Log Kp = log $(P_{\mathrm{Na}})^2/P_{\mathrm{Na}_2}$	0·857	1·339	1·702	1·981	2·204

The partial pressures of atoms and molecules in the saturated vapour at the boiling point predicted by this equation (1162°K.) are 658 mm. and 102 mm. respectively. More recent calculations of the dissociation constant, also using spectroscopic data, have been carried out by Benton and Inatomi.[179] Their values for log Kp include -8·66 at 298·1°K., 0·34 at 1000°K., 2·31 at 2000°K. and 2·77 at 2600°K. (partial pressures in atmospheres). Values for the molecular weight of sodium vapour between 100° and 2600°K. (at a total pressure of one atmosphere) based on these last results are included in Table XVI (see page 397). Ladenberg and Thiele[155] calculated dissociation constants and combined them with other vapour pressure data to obtain the equation:-

$$\log_{10} p_{\mathrm{Na}}\,(\mathrm{mm.}) = -5701/T + 11{\cdot}329 - 1{\cdot}178 \log T.$$

At the boiling point (1156°K.) this gives $p_{\mathrm{Na}} = 614$ mm. and $p_{\mathrm{Na_2}} = 145$ mm. Lewis,[180] using a magnetic deflection method, obtained experimental values for the dissociation constant ranging from log Kp (partial pressures in mm.Hg) = 0·936 at 630°K. to log Kp = 2·06 at 762·5°K. (equivalent to −1·945 to −0·82 for partial pressures in atmospheres). From calculations based on the results of Lewis, the partial pressures of sodium atoms and molecules have been expressed by the equations:-[175]

$$\log_{10} p_{\mathrm{Na}} = -5728/T + 11{\cdot}641 - 1{\cdot}27 \log T$$

$$\log_{10} p_{\mathrm{Na_2}} = -7020/T + 8{\cdot}149.$$

The accuracy of the former equation is stated to be ± 10% between 370° and 850°K., and ± 20% between 370° and 1200°K.; that for the latter is ± 50% between 600° and 800°K.

Determinations of the vapour density of sodium made between 570° and 706°C. using a dynamic method have given values for the apparent molecular weight which are lower than those predicted by spectroscopic data.[167,181]

From the slope of his log Kp − $(1/T)$ curve, Lewis[180] calculated a value of 16·5 kg.-cal./g.mole (≡ 0·73 e.V.) for the heat of dissociation or dissociation energy of the sodium molecule. From the magnetic rotation spectrum, Loomis and Nusbaum[182] obtained a value of 0·76 ±0·02 e.V. An earlier determination[183] of the heat of dissociation from band spectra data gave a much higher value of 26·8 kg.-cal./g.mole (≡ 1·16 e.V.). Rodebush[184] in 1932 considered that the true value was in the interval 0·76–0·78 e.V. Herzberg in 1950[185] listed 0·73 e.V. as the best value of the dissociation energy. The U.S. Bureau of Standards selected value[187] for the heat of formation of diatomic sodium vapour is 34·58 kg.-cal./g.mole at 0°K. and 33·97 kg.-cal./g.mole at 298·16°K., while the free energy of formation at the latter temperature is 24·85 kg.-cal./g.mole. A later publication[187a] gives the heat of formation of diatomic vapour as 34·31 kg.-cal./g.mole at 0°K. and 33·705 kg.-cal./g.mole at 298·16°K.; the free energy of formation at 298·16°K. is given as 24·637 kg.-cal./g.mole.

Heats of Vaporization and Sublimation

Values for the heat of vaporization of sodium at 0°K., calculated from vapour pressure data, include 25·8 kg.-cal./g.-atom,[186] 25·9 kg.-cal./g.-atom,[170] 26·0 ± 0·13 kg.-cal./g.-atom,[155] and 26·2 ± 0·13 kg.-cal./g.-atom.[166] Between 540° and 840°K., Ladenberg and Minkowski[170] gave the equation ΔH(kg.-cal./g.-atom) = $25{\cdot}95 - 2{\cdot}34 \times 10^{-3}T$, while Rodebush and De Vries[165] gave the heat of vaporization near the melting point as 24·6 kg.-cal. Using the composite data of several workers, Kelley[174] has represented the heat of vaporization to monatomic vapour by the equation:-

$$\Delta H(\text{kg.-cal./g.-atom}) = 26{\cdot}124 - 2{\cdot}53 \times 10^{-3}T,$$

and the free energy of vaporization by:-

$$\Delta F(\text{kg.-cal./g.-atom}) = 26{\cdot}124 + 5{\cdot}83 \times 10^{-3}T \log T - 3{\cdot}993 \times 10^{-2}T.$$

For the temperature at which the pressure of atoms becomes one atmosphere (1187°K.), ΔH is 23·121 kg.-cal./g.-atom and ΔS is 19·48 g.-cal./g.-atom.[174]

The U.S. Bureau of Standards[187] selected value for the heat of sublimation of sodium to monatomic vapour is 26·05 kg.-cal./g.-atom at 0°K. and 25·98 kg.-cal./g.-atom at 298·16°K., while the value for the free energy of sublimation is 18·67kg.-cal./g.atom at 298·16°K. A later publication[187a] gives the heat of sublimation to monatomic vapour as 25·92kg.-cal./g.atom at 0°K. and 25·857kg.-cal./g.atom at 298·16°K., and the free energy of sublimation as 18·574kg.-cal./g.atom at 298·16°K. Kelley[174] has given the equations:-

$$\Delta H(\text{kg.-cal./g.-atom}) = 26{\cdot}199 - 0{\cdot}4 \times 10^{-4}T - 2{\cdot}68 \times 10^{-6}T^2$$

$$\text{and } \Delta F(\text{kg.-cal./g.-atom}) = 26{\cdot}199 - 0{\cdot}9 \times 10^{-4}T \log T + 2{\cdot}68 \times 10^{-6}T^2 - 2{\cdot}638 \times 10^{-2}T$$

for the heat and free energy of sublimation respectively. These lead to $\Delta H_{298\cdot1}$ = 25·949 kg.-cal./g.-atom and $\Delta F_{298\cdot1}$ = 18·639 kg.-cal./g.-atom. Quantum mechanical computations of the heat of sublimation or cohesive energy of sodium have been made by a number of authors[43,44,50-53,55-55b] (see page 381).

Specific Heat, Enthalpy and Entropy

Specific Heat.

The specific heat of sodium at low temperatures has been studied by several investigators. Simon and Zeidler[188] in 1926 made measurements above 17°K.:-

T, °K.	16·95	20·04	23·35	26·17	29·4
C_p, g.-cal./g.-atom/°C.	0·592	0·856	1·21	1·55	1·93
C_v, g.-cal./g.-atom/°C.					
T, °K.	34·6	41·4	49·5	58·1	117·6
C_p, g.-cal./g.-atom/°C.	2·47	3·09	3·79	4·27	5·64
C_v, g.-cal./g.-atom/°C.		3·09	3·78	4·24	5·50

More recently (1950), Pickard and Simon[189] made measurements between 2° and 25°K. In the overlapping temperature range the values were slightly higher than those obtained previously.

T, °K.	2	4	6	7	8	10
C_v, g.-cal./g.-atom/°C.	0·0055	0·0135	0·059	0·124	0·093	0·140
T, °K.	12	14	16	18	20	25
C_v, g.-cal./g.-atom/°C.	0·250	0·385	0·54	0·71	0·90	1·45

There is an anomalous behaviour at about 7°K. where a peak occurs in the specific heat–temperature curve. A study of the specific heat at temperatures below 1°K. has also shown a pronounced peak at about 0·87°K.[190] A low-temperature martensitic-type transformation (see page 377) has been suggested as the cause of this behaviour. Parkinson and Quarrington,[191] employing sodium specimens that had been allowed to self-anneal for several days, observed no peak in the range 1·4 to 20°K., and they suggest that in the above two instances where anomalies have been observed the specimen was probably in a state of strain. The specific heat values obtained in this last study were:-

T, °K.	1·5	2·0	3·0	4·0	5·0
C_p, g.-cal./g.-atom/deg.	0·00105	0·00180	0·00445	0·00985	0·0195
T, °K.	6·0	7·0	8·0	10·0	12·0
C_p, g.-cal./g.-atom/deg.	0·0345	0·052	0·078	0·142	0·250

T, °K.	14·0	16·0	18·0	20·0
C_p, g.-cal./g.-atom/deg.	0·385	0·535	0·710	0·900

They agree well with those of Pickard and Simon between 10° and 20°K., but at lower temperatures they are considerably below the earlier values. Measurements by Roberts[191a] over the range 1·3 to 20°K. have also shown a monotonic increase of specific heat with temperature, but the values recorded were between 5 and 10% lower than those of Parkinson and Quarrington.[191] Plots of C_p/T against T^2 for the results of Parkinson and Quarrington[191] and of Roberts[191a] lead to values of 0·00043 T g.-cal./g.atom^{-1}deg.$^{-1}$ and (0·000328 ± 0·00001)T g.-cal./g.atom^{-1}deg.$^{-1}$ respectively for the electronic specific heat. Bidwell[192] calculated the specific heat of sodium at temperatures between that of liquid hydrogen and 70°C. using cooling curves obtained in a study of the thermal conductivity of sodium. At temperatures above –125°C. the atomic heat at constant volume exceeded the Dulong and Petit maximum, and it was suggested that the excess represented latent heat of crystallization required for disintegration of the crystal lattice. In other measurements extending from 55° to 315°K. it was found that in the region between 150° and 250°K. the specific heat curve showed a very slight hump which rose to a peak of approximately ½% above the smooth line joining the upper and lower parts of the curve.[192a] A hysteresis effect was also found in this region.[192a] Table XIII[189] gives values for the specific heat of sodium up to 300°K. based on the measurements of several workers.

TABLE XIII.- THERMODYNAMIC PROPERTIES OF SODIUM AT LOW TEMPERATURES

Temp. °K.	C_p g.-cal./g.-atom/°C.	H_T–H_0 g.-cal./g.-atom	S_T–S_0 g.-cal./g.-atom/°C.	–(F_T–F_0) g.-cal./g.-atom

In reviewing thermal data up to 1948, Kelley[193] gave the following equation as representing the specific heat of solid sodium between 298 and 371° with an accuracy of ± 1%:-

$$C_p = 5{\cdot}00 + 5{\cdot}36 \times 10^{-3}T \text{ (}C_p \text{ in g.-cal./g.-atom, } T \text{ in °K.).}$$

Precise measurements under saturation conditions over the range 0° to 900°C. have led to the following equations for the heat capacity of solid and liquid sodium respectively:-[154] ($C_{\text{sat.}}$ in absolute joules/g.; t in °C.)

$$C_{\text{sat.}}\ (\text{solid}) = 1{\cdot}19926 + 6{\cdot}494 \times 10^{-4}t + 1{\cdot}0531 \times 10^{-5}t^2 \quad (0 \text{ to } 97{\cdot}8°\text{C.})$$

$$C_{\text{sat.}}\ (\text{liq.}) = 1{\cdot}43674 - 5{\cdot}8049 \times 10^{-4}t + 4{\cdot}6229 \times 10^{-7}t^2 \quad (97{\cdot}8 \text{ to } 900°\text{C.}).$$

Values calculated using these equations, for which the probable error is ± 0·3 to 0·4%, are given in Table XIV. Quenching and annealing treatments did not change the specific heat by more than 0·2%, which is within the limits of the experimental error.

TABLE XIV.- SPECIFIC HEAT, ENTHALPY AND ENTROPY OF SODIUM BETWEEN 0° AND 900°C.

The specific heat of solid sodium rises markedly as the melting point is approached. There is a fall on melting, and the specific heat of the liquid then decreases with increase of temperature to a minimum at about 650°C. The rise in the specific heat prior to melting is characteristic of the alkali metals.[194] Itaka,[195] who made measurements on solid sodium and on liquid sodium between 125 and 290°C., reported an increase in the specific heat on melting, but this is not borne out by the above recent work. Less precise values for the specific heat of liquid sodium at 121° and 178°C. have been obtained by measuring the adiabatic temperature-pressure coefficient.[196] A recent table[74] based on the results of Ginnings *et al.*[154] lists specific heats for liquid sodium in B.t.u./lb./°F. at 5°F. intervals between the melting point (208°F.) and 1500°F.

From the vibration frequency, Kelley[193] represented the heat capacity of diatomic sodium vapour by the equation:-

$$C_p = 8{\cdot}94 - 0{\cdot}08 \times 10^5 T^{-2} \text{ (accuracy } \pm 0{\cdot}5\% \text{ between } 298° \text{ and } 2000°\text{K.).}$$

Values, calculated from spectroscopic data, for the heat capacity of both monatomic and diatomic sodium vapour at one atmosphere pressure are included in Table XV[179] (see page 397). Independent calculations have given very similar values.[187a]

Sodium, in common with the other alkali metals, does not obey the Debye formula, which requires a constant value for the Debye characteristic temperature, θ. Instead, θ has a value of about 90° at 2°K., 160° at 40°K. and 150°

at 120°K. Various attempts have been made to account for the deviations from the Debye theory and to calculate specific heats in agreement with experiment. Simon and Zeidler[188] suggested the existence of thermally excited quantum jumps to explain their observed behaviour, but this view has now been displaced (cf. Lithium, page 39). The generalized work of Blackman[197] showed that large variations in θ could be accounted for by a theory of specific heats which takes into account the atomic structure. Following this, Fuchs[97,98] showed that if dispersion is neglected - as is the case in the Debye theory - the anisotropy of the alkali metals gives rise to the type of divergence from the Debye formula observed with sodium. Specific heats in fair agreement with experiment have been calculated by evaluating the four discrete frequencies of atomic vibration in terms of the elastic constants of the sodium crystal, and representing the residual degrees of freedom not covered by these modes by a Debye function with a correspondingly reduced characteristic temperature.[198] More recent treatments[199,200] have been concerned also in accounting for the behaviour below 25°K., where θ falls considerably. Bauer[199] derived the frequency spectrum using a two force-constant model and from this calculated the lattice part of the specific heat as a function of temperature. Closer agreement with experiment was achieved by Bhatia[200] who derived the frequency spectrum, and hence the specific heat, using a three force-constant model. He suggests that for a metal like sodium, which is neither elastically isotropic nor in conformity with the Couchy relation $C_{12} = C_{44}$, some three force-constant model is necessary.

Characteristic temperature values have been given by a number of authors in treatments of specific heat and other data.[5,96-98,189,191,191a,192a,197-201b,205a] A recent detailed study of characteristic temperature data has used four different methods for calculating θ_D, the Debye characteristic temperature from thermodynamic data and θ_R from electrical resistance data.[201,202] At temperatures below 100°K. the various methods lead to values of about 170° for both θ_D and θ_R, but at higher temperatures the different methods give widely divergent results. Thus, while θ_D actually becomes negative above 200°K. when derived conventionally from C_v, it decreases by only 13% up to 300°K. when derived from the thermal energy.

Heat Content or Enthalpy.

Values for the heat content or enthalpy of solid and liquid sodium over the ranges 0°K.–300°K. and 0°C.–900°C. are included in Tables XIII[189] and XIV.[154] The data of Table XIV were obtained by dropping samples of sodium, sealed in stainless steel cylinders, from a constant temperature into a Bunsen ice calorimeter, and the following equations were derived from them. (Temperature is in degrees C., the enthalpy in absolute joules per g., and the estimated probable error is given as ± 0·1–0·2%.)

$$H_t\,(\text{solid}) - H_0\,(\text{solid}) = 1{\cdot}19926t + 3{\cdot}247 \times 10^{-4}t^2 + 3{\cdot}510 \times 10^{-6}t^3 \qquad (0 \text{ to } 97{\cdot}80^\circ\text{C.})$$

$$H_t\,(\text{liq.}) - H_0\,(\text{solid}) = 98{\cdot}973 + 1{\cdot}436744t - 2{\cdot}90244 \times 10^{-4}t^2 + 1{\cdot}54097 \times 10^{-7}t^3 + 24{,}000\,\mathrm{e}^{-13{,}600/t+273} \qquad (97{\cdot}80^\circ \text{ to } 900^\circ\text{C.}).$$

Simplified equations based on the above data have been used to list the enthalpy of sodium in B.t.u./lb. at intervals of 5°F. between the melting point and 1500°F.[74] Other equations for solid and liquid sodium based on older experimental values are given by Kelley.[193]

For diatomic sodium vapour, Kelley[193] has given the equation:-

$$H_T - H_{298{\cdot}16} = 8{\cdot}94\,T + 0{\cdot}08 \times 10^5 T^{-1} - 2692$$

TABLE XV.- THERMODYNAMIC FUNCTIONS FOR MONATOMIC AND DIATOMIC SODIUM VAPOUR IN THEIR STANDARD STATE OF ONE ATMOSPHERE PRESSURE

Subscript (1) refers to monatomic sodium vapour.
Subscript (2) refers to diatomic sodium vapour.

as representing the enthalpy (in g.-cal./g.-mole) between 298° and 2000°K. with an accuracy of ± 0·5%. By using spectroscopic data and the methods of statistical mechanics, and by assuming the vapours to be ideal gases at a pressure of one atmosphere, the values of Table XV have been calculated[179] for the enthalpy and other thermodynamic functions of both monatomic and diatomic sodium vapour. Values calculated by Evans *et al.*[187a] in a review of the thermodynamic properties of the alkali metals are very similar.

The molecular weight, enthalpy and entropy of the equilibrium mixture of monatomic and diatomic sodium vapour at a total pressure of one atmosphere are shown in Table XVI.[179] In obtaining the enthalpy values of this Table, the zero point energies of monatomic and diatomic sodium vapour were taken as 26·05 kg.-cal./mole and 35·26 kg.-cal./mole respectively.

TABLE XVI. - MOLECULAR WEIGHT, ENTHALPY AND ENTROPY OF THE EQUILIBRIUM MIXTURE OF MONATOMIC AND DIATOMIC SODIUM VAPOUR AT A TOTAL PRESSURE OF ONE ATMOSPHERE

2600	23·036	39·001	47·543

A Mollier (enthalpy-entropy) diagram has been prepared for saturated and wet sodium vapour.[203]

Entropy.

From heat capacity data available up to 1948, Kelley[204] gave the entropy of solid sodium at 298·16°K. as 12·23 ± 0·10 g.-cal./g.-atom/°K. of which 0·09 is the extrapolation below 12·6°K. The U.S. Bureau of Standards selected value is 12·2 g.-cal./g.-atom/°K. at 298·16°K.[204] Entropy values for solid and liquid sodium at lower and higher temperatures are included in Tables XIII[189] and XIV.[154]

For monatomic sodium vapour, the Sackur equation - to which must be added $R\ln 2$ to account for the multiplicity in the lowest energy state - gives 36·72 ± 0·01 g.-cal./g.-atom/°K. for the entropy at 298·16°K.[204] The molecular constants of diatomic sodium vapour lead to $S^\circ_{298\cdot16}$ = 54·90 ± 0·10 g.-cal./mole/°K., of which 2·57 is the vibrational contribution and 52·33 the translational and rotational contribution.[204] Table XV contains values calculated from spectroscopic data for the entropy of both monatomic and diatomic sodium vapour, while Table XVI gives entropy values for the equilibrium mixture of monatomic and diatomic sodium vapour at a total pressure of one atmosphere.[179] Entropies for monatomic and diatomic sodium vapour calculated by Evans *et al.*[187a] are almost identical with those of Table XV.

Temperature-entropy and Mollier (enthalpy-entropy) charts have been constructed[203] for the system:-

$$2\text{Na(liq.)} \rightleftharpoons 2\text{Na(vapour)} \rightleftharpoons \text{Na}_2\text{(vapour)}$$

Free Energy.

Free energy data for sodium in the solid, liquid and gaseous states are included in or may be derived from the data of Tables XIII,[189] XIV,[154] XV[179] and XVI.[179]

Thermal Conductivity

Values for the thermal conductivity of solid sodium, obtained by using a modified Forbes bar method, are shown in Table XVII.[192]

TABLE XVII. - THERMAL CONDUCTIVITY OF SOLID SODIUM

Temp., °C.	−240	−200	−150	−100	−50	0	+50	+75
k (watt cm.$^{-1}$/°C.$^{-1}$)	1·69	1·58	1·42	1·28	1·17	1·40	1·21	1·13

From −240° to −40°C. there is a linear decrease in the conductivity, but between −40° and 0°C. a discontinuity occurs and the conductivity increases from 1·17 to 1·40 watt cm.$^{-1}$ °C.$^{-1}$ At higher temperatures the thermal conductivity again decreases with increase of temperature. Other measurements have been made between ~4° and 90°K.[205] and between 2° and 16°K.[205a] At temperatures below 16°K. the thermal conductivity is represented by the equation:-

$$1/k = A/T + BT^2,$$

and there is a maximum conductivity at about 4–5°K. With k in watt cm.$^{-1}$ °C.$^{-1}$ and T in °K., Berman and MacDonald[205] obtained a value of $3{\cdot}8 \times 10^{-4}$ for B, whilst A varied with the impurity content between 0·42 and 0·06. The later work[205a] gave $B = 3{\cdot}5 \times 10^{-4}$ and $A = 0{\cdot}06$–$0{\cdot}07$. Hall[206] used a guard ring method to measure the conductivity of solid and liquid sodium between 85° and 210°C.: his results for the liquid between 100° and 210°C. were represented by the equation:-

$$k = 0{\cdot}860\,[1 - 0{\cdot}338 \times 10^{3}\,(t - 100) - 2{\cdot}6 \times 10^{6}\,(t - 100)^2],$$

k being in watt cm.$^{-1}$ °C.$^{-1}$ and t in °C. Extension of the experimental curves to the freezing point gave 0·861 watt cm.$^{-1}$ °C.$^{-1}$ for liquid sodium and 1·120 watt cm.$^{-1}$ °C.$^{-1}$ for solid sodium at this temperature. The ratio of the thermal conductivities of the solid and liquid is thus 1·30, in good agreement with an older value of 1·31.[207] Employing the relationship between electrical and thermal conductivity – the Lorentz number – the thermal conductivity of liquid sodium at its melting point has been estimated as 0·23 to 0·30 g.-cal.cm.$^{-1}$ sec.$^{-1}$ °C.$^{-1}$ (0·96 to 1·25 watt cm.$^{-1}$ °C.$^{-1}$).[208] More recent measurements on liquid sodium have been made between ~180° and 510°C. and the experimental values were closely fitted by the equation $k/C_p d^{5/3}$ = constant, where k is the thermal conductivity, C_p the specific heat and d the density.[209] This equation has been used to extrapolate values up to 900°C. (Table XVIII). Thermal conductivities calculated from measurements[70a] of thermal diffusivity ($= k/C_p d$) between the melting point and 700°C. show fair agreement with the values of Table XVIII.

TABLE XVIII. - THERMAL CONDUCTIVITY OF LIQUID SODIUM

Temp., °C.	k watt cm.$^{-1}$/°C.$^{-1}$	Temp., °C.	k watt cm.$^{-1}$/°C.$^{-1}$
100	0·860[206]	600	0·631
200	0·816	700	0·600
300	0·759	800	0·573
400	0·710	900	0·552
500	0·667		

The thermal conductivity of sodium has been related to the specific heat and absolute temperature, and the lattice and atomic contributions to the thermal conductivity at 0°C. are given as 0·092 and 0·169 g.-cal.cm.$^{-1}$sec.$^{-1}$ °C.$^{-1}$ respectively.[210] Several authors[205,210a–c] have discussed the discrepancies between experimental values for the thermal conductivity of sodium at low temperatures and the predictions of the electron theory of metals.

Thermal conductivities have also been reported for sodium amalgams containing 70 to 94 atoms % Na[206] and for sodium–potassium alloys.[70a,72,211]

The high thermal conductivity of sodium – coupled with other properties such as its reasonably low melting point and low vapour pressure even at fairly high temperatures – gives the metal very useful heat transfer properties. Its Prandtl number, *i.e.* the product of the specific heat at constant pressure and the viscosity divided by the thermal conductivity, is 0·0072 at 200°C. and 0·0038 at 700°C.[72] Heat transfer coefficients for liquid sodium have been studied recently, especially in connexion with the use of liquid sodium as a heat transfer medium for developing power from nuclear reactors.[212-214] In general reviews of this field[212-213] numerous references to other work are given. Sodium–potassium alloys have lower thermal and electrical conductivities than sodium but they are nevertheless useful as heat transfer media since they are liquid at room temperature. Sodium itself appears to be the most suitable coolant for nuclear power reactors.[215]

Electrical Resistance

Bidwell[192] determined the specific resistance of sodium at 0°C. to be $0{\cdot}426 \times 10^{-5}$, and combining this figure with his earlier measurements of relative resistance[216] he obtained the following values for specific conductance:-

Temp., °C.	–240	–200	–150	–100	–50	0	50	75
σ, ohm^{-1}cm.$^{-1}$ × 10^{-4}	226·0	133·3	67·0	43·4	31·4	23·5	18·9	17·1

There is a marked increase in the electrical resistance as the melting point is approached[216] (Fig. 3). This and the similar rise in specific heat on approaching the melting point (see page 395) have been discussed in terms of lattice defects.[216a] Using sodium produced by electrolysis through glass, Nielsen[217] found the specific resistance of the solid at 30–90°C. to be given by: $4661 \times 10^{-9} \times (1 + 0{\cdot}00484t)$ and that for the liquid below 160° by $9828 \times 10^{-9} \times (1 + 0{\cdot}00354(t - 100) + 0{\cdot}00000039(t - 100)^2)$. Woods,[205a,217a] who made measurements in the region 4° to 15°K. on samples of sodium for which the residual resistivity was $1{\cdot}38 \times 10^{-9}$ ohm cm., found that after subtracting the residual resistivity the 'ideal' resistivity was given by

$$\rho = 8{\cdot}6 \times 10^{-16} T^6 \text{ ohm cm. between } 4° \text{ and } 9°\text{K.}$$

and by

$$\rho = 8{\cdot}4 \times 10^{-15} T^5 \text{ ohm cm. between } {\sim}8° \text{ and } 15°\text{K.}$$

From other measurements[205] on samples with residual resistivities of 10^{-8} to 10^{-9} ohm cm. the 'ideal' resistivity below 15°K. was represented by

$$\rho = 5{\cdot}37 \times 10^{-15} T^5 \text{ ohm cm.}$$

Several other workers have measured the resistance of sodium at low temperatures relative to that at 0°.[218-221] Woltjer and Onnes[218] obtained $R/R_{273°\text{K}} = 0{\cdot}5672$ at 170·87°K., 0·3168 at 108·72°K. and 0·1055 at 56·77°K. It was found by Meissner and Voigt,[219] who made measurements down to 1·23°K., and by MacDonald and Mendelssohn,[221] who made continuous measurements over the range 1·5° to 20°K., that below liquid helium temperature (4·2°K.) the resistance was substantially constant. The magnitude of the 'residual' resistance is an indication of the purity of the samples used.

Meissner and Voigt obtained a residual resistance of $R/R_{273°K.} = \sim 3 \times 10^{-3}$, while MacDonald and Mendelssohn using a purer sodium sample obtained $\sim 7 \times 10^{-4}$. It is customary in calculating $R/R_{273°}$ values to subtract the residual resistance: when this is done the results of the various workers are in close accord. Thus at 20·4°K. the investigations cited give $R/R_{273} = 0{\cdot}0034_7$[219] and 0·00326.[221] Table XIX contains some values of low-temperature resistance ratio corrected for residual resistance.

TABLE XIX. - RELATIVE ELECTRICAL RESISTANCE OF SODIUM AT LOW TEMPERATURES

Temp., °K.	4·2	8·1	9·65	11·05	13·1	14·1
$R/R_{273°K.}$	0·00000[221]	0·00005[221]	0·000 10[221]	0·000 17[221]	0·00036[221]	0·00051[221]
Temp., °K.	15·95	20·4	77·6	87·8	90·0	
$R/R_{273°K.}$	0·00098[221]	0·000326[221]	0·1849[219]	0·2279[219]	0·2420[221]	

Kamerlingh Onnes and co-workers[222,223] showed that sodium was not superconducting down to a temperature of 1·5°K., and later work[224,225] has shown that this is also true down to 0·09°K.

Kapitza[226] found that the application of a transverse magnetic field of 300 kilogauss increased the resistance of a sodium wire by 7% at 90°K. and by less than 2% at room temperature. A more detailed study of the effect of transverse and longitudinal fields on the electrical resistance of sodium has been made by Justi[220,227] who used field strengths up to 40 kiloguass at temperatures between 14° and 78°K. Percentage resistance increases of up to 50% were observed on applying the field.[220]

Resistivity measurements on very pure sodium in capillaries with diameters between 15 and 66μ and at temperatures between 20 and 4·2°K. have shown a size-effect, the resistivity increasing with decreasing diameter of the wire.[228] It has also been found recently that under these conditions application of transverse and longitudinal magnetic fields produces a decrease in the resistivity: for large longitudinal fields the resistivity tends towards its bulk value.[228,229] The conditions for this effect are such that the diameter of the specimen, the free path of the conduction electrons, and the radius of the circular orbits of the electrons in the magnetic field are all of comparable orders of magnitude. This behaviour, which contrasts with that in the bulk material where magnetic fields cause increases in resistivity, has been treated theoretically.[230-232]

Earlier measurements (Mellor,II,460) of the effect of pressure on the electrical resistance of sodium have been extended to higher pressures.[233,234,430] Table XX shows values to 100,000 kg./cm.^{2}.[430] A very flat minimum occurs in the curve in the region of 45,000 kg./cm.^{2}

TABLE XX. - EFFECT OF PRESSURE ON THE ELECTRICAL RESISTANCE OF SODIUM

Pressure, kg./cm.$^2\times 10^{-3}$	0	10	20	30	40	50	60	70	80	90	100
R/R_0	1·0	0·618	0·483	0·413	0·392	0·390	0·399	0·412	0·430	0·452	0·479

A wave-mechanical view of the effect of pressure on the electrical resistance of sodium has been given by Frank.[235]

Calculations of the electrical resistance of sodium based on electronic theories of metallic conduction have, in general, shown fairly close agreement with experiment.[236-239] The temperature coefficient of resistance[237,240] and the change of resistance on melting[240] have also been treated mathematically.

Thermoelectric Properties

Bidwell[216] measured the thermoelectric power of sodium relative to platinum between -180° and +150°C. His results are shown in Fig. 3. Above -40°C. the thermoelectric power–temperature curve deviates from the straight line which it follows from -180°C. There is a marked increase in thermoelectric power as the melting point is approached; thereafter it decreases with rise of temperature.

The thermoelectric force of sodium against lead down to 4·2°K. was studied by MacDonald and Pearson,[241,242] who converted their values to the absolute e.m.f. scale using the absolute thermoelectric force of lead measured by Borelius *et al.*[243] Resultant values for the absolute thermoelectric force of sodium (interpolated from their graphically presented results) are:-

T, °K.	0	10	20	30	40	50	60	70	80
Microvolts	0	0	-7	-18	-33	-52	-74	-96	-120

Down to ~15°K. the thermoelectric power is directly proportional to the temperature, but at lower temperatures there are indications of a trend to a higher power law.[241] The thermoelectric effect of the alkali metals has been discussed from the viewpoint of the electron theory of metals.[241,242,244]

Magnetic Properties

Sodium, like the other alkali metals, is paramagnetic and its susceptibility varies only slightly with temperature. More recent determinations have given values for the mass susceptibility rather higher than that, $0{\cdot}51 \times 10^{-6}$, quoted previously (Mellor,II,460). Using the Gouy method, Lane and Bieler[245] obtained $0{\cdot}65 \times 10^{-6}$ for the mass susceptibility at room temperature. The value remained constant for field strengths between 8 and 12 kilogauss showing the sample to be free from ferromagnetic impurity. Other workers[246] obtained $0{\cdot}63 \times 10^{-6}$ for the mass susceptibility of sodium at room temperature, and practically the same value was found at liquid air temperature. Klemm and Hauschulz[247] obtained $0{\cdot}66 \times 10^{-6}$ at ordinary temperatures. Recently, Bowers,[248] also using the Gouy method, found the mass susceptibility at room temperature to be $0{\cdot}70 \times 10^{-6} \pm 0{\cdot}03 \times 10^{-6}$ and observed that the susceptibility decreased by 4·5% between room temperature and 55°K. Sucksmith[249] found $0{\cdot}62 \times 10^{-6}$ for the mass susceptibility at 500°C. Bohm and Klemm[9] have given the following values for the atomic susceptibility (mass susceptibility × atomic weight) of sodium between -183 and +100°C.:-

T, °C.	-183	-78	+20	+100
$\chi_{At} \times 10^6$	15·2	15·4	15·6	16·4

Theoretical computations of the susceptibility of sodium agree fairly well with experiment.[250–252] Samson and Seitz,[252] on the basis of the electronic structure, calculated the volume susceptibility to be $0{\cdot}70 \times 10^{-6}$ made up as follows: spin paramagnetism, $1{\cdot}11 \times 10^{-6}$; free electron diamagnetism, $-0{\cdot}23 \times 10^{-6}$; ion core diamagnetism, $-0{\cdot}18 \times 10^{-6}$. A recent correction[253] has slightly increased the free electron diamagnetism term, but has little effect on the nett susceptibility. Electron spin resonance absorption has been observed in bulk and dispersed sodium.[130 a-b, 253 a-c] Line shapes and width, relaxation times, and splitting factors have been determined. That part of the volume susceptibility arising from conduction electron spin was calculated by Pines[253 d] to be $0{\cdot}85 \times 10^{-6}$ c.g.s. units.

Refs. p. 411

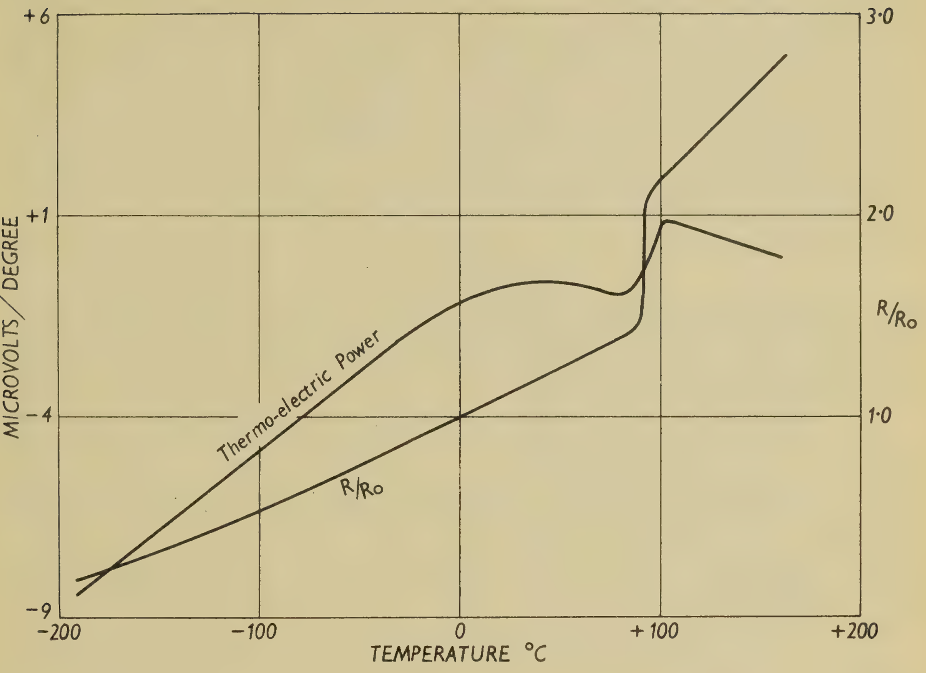

FIG. 3. RELATIVE RESISTANCE AND THERMOELECTRIC POWER CURVES FOR SODIUM

Numerous authors have attempted to evaluate the contribution of the sodium ion to the diamagnetism of its salts either by making use of experimental data for the salts or by applying theoretical methods. The various treatments have, however, given widely differing values. Values for the susceptibility of the sodium ion in solution obtained from measurements on its salts include -10·4,[254] -8·5,[255,256] -7·7,[257,258] -7·0,[259] -5·6[260,261] and -5·2[262] (all to be multiplied by 10^{-6}), while values for the Na$^+$ ion in crystals include -7·6 × 10^{-6} [263] and -6·1 × 10^{-6}.[264,265] Theoretical treatments have given the following values for the free Na$^+$ ions: -15·0,[266] -10·89,[267] -10,[268] -7·9,[269] -5·47,[270] -5·05,[271] -4·2,[262,272,273] -4·1,[265] -3·74,[274] -2·9[275] (all to be multiplied by 10^{-6}). Other values for the free ion include -9·0,[255,256] -8·2[257,258] and -7·5[259] (all to be multiplied by 10^{-6}). Klemm[276,277] in a review of the field has given -2·3 × 10^{-6} as the most probable value for the susceptibility of the Na$^+$ ion in solution, -4·6 × 10^{-6} for the Na$^+$ ion in crystals and -5·0 × 10^{-6} for the free Na$^+$ ion. Another contemporary survey[278] recommends -6·8 × 10^{-6} for the Na$^+$ ion but does not distinguish between the ion in solution and in crystals.[279] Methods of obtaining ionic susceptibilities and/or the values which have resulted from them have been reviewed by several authors.[276,278,280-282]

By passing a beam of sodium atoms through a non-homogeneous magnetic field, as in the classical experiments of Stern and Gerlach, sodium is found to have a magnetic moment of 1 Bohr magneton.[283-285] The behaviour of a beam of alkali atoms when passed through a rotating magnetic field has been examined both experimentally[286] and theoretically.[287,288] The best values for the magnetic moment of the ^{23}Na nucleus lie between 2·215 and 2·217 nuclear magnetons;[289-291] other values vary between 2·08 and 2·6 nuclear magnetons.[292,293]

Nuclear magnetic resonance and the nuclear moment of ^{23}Na have been studied and discussed by a number of other authors.[140-141b, 294-306] Knight[301] found that the nuclear magnetic resonance frequency of sodium in the metallic state was about 0·1% higher than that of sodium in its salts. At room temperature the resonance frequency of sodium in its salts at the field used was 10·123 Mc./sec. and the frequency shift in the metal was 10·5 Kc./sec. The shift has been attributed to the interaction of the magnetic moment of the nucleus with the magnetic moments of the conduction electrons.[302] Between 75° and 25° K. the frequency shift has been observed to drop by about 10% of its value at 300° K.[305]

The spin of the ^{23}Na nucleus has a value of 3/2.[293,307,308]

Electrode Potentials

The chemical reaction between sodium and water prevents a direct determination of the standard electrode potential of sodium. An indirect method due to Lewis[309] may be employed, however. This involves measuring the potential difference of two cells:-

(a) Pure sodium against a dilute sodium amalgam when both are immersed in a solution of sodium ions in a non-aqueous solvent inert towards sodium.

(b) The dilute amalgam in an aqueous sodium salt relative to a calomel or other reference electrode.

The European convention regarding the sign of the electrode potential is followed in all the values below. A recalculation[310] of the results of Lewis and Kraus,[309] who used:-

Na (solid) | NaI in ethylamine | Na (0·206% amalgam)

as their non-aqueous cell, has given −2·7126 V. for the standard electrode potential of sodium at 25°C. on the hydrogen scale. More recent measurements by Smith and Taylor[311] on the cells:-

Na (solid) | NaI in dimethylamine | Na (0·0651% amalgam) and

Na (0·0651% amalgam) | NaCl (0·05 or 0·1 M.); AgCl (solid) | Ag (solid)

between 5 and 40°C. have led to the expression:-

$$E^{\circ}_{\mathrm{Na}} = -2{\cdot}71324 - 0{\cdot}7532 \times 10^{-3}\,(t - 25) - 0{\cdot}688 \times 10^{-6}\,(t - 25)^2.$$

Trümpler[312] has developed a glass-membrane sodium electrode, and from measurements on the cell:-

Na | Glass | NaCl (satd. soln.) | Reference electrode

has obtained −2·72 V. for the sodium standard potential. The sodium/glass electrode has also been studied in fused salts,[313,313a] and a sodium/sodium chloride (solid) electrode has been studied in aqueous solution.[312] More recent measurements[314] of sodium amalgam potentials obtained by a glass membrane technique have been combined with the values of Bent and Swift[315] (see below) for the activity of sodium in amalgams to give −2·7109 ± 0·0005 V. for the standard potential of sodium. Thermodynamic calculations of the standard potential have been made by Drossbach[316-318] who finally arrived at E°_{Na} = −2·72 V. From measurements of the decomposition voltages of fused sodium halides, a value of −2·454 V. has been given for the potential of sodium at 18°C.[319] The determination of the absolute electrode potential of sodium has been discussed,[320,321] and using spectroscopic and thermodynamic data, Gapon[321] has calculated its value as +1·18 V.

The best representative values for the standard electrode potentials of the alkali metals in aqueous solution at 25°C. are compared below:-[322]

Lithium	−3·01 V.
Sodium	−2·713 V.
Potassium	−2·92 V.
Rubidium	−2·92 V.
Cæsium	−2·92 V.

Sodium is seen to have the least negative potential of the alkali metals.

A value of −0·39 V. has been calculated for the potential of the ionic double layer at sodium which leads to −2·32 V. for the potential of zero charge or of the maximum of the electrocapillary curve.[322a]

In most non-aqueous solvents the standard electrode potential of sodium is less negative than in water. The standard potential at 25°C. (relative to $E^{\circ}_{\mathrm{H}_2} = 0$ in the respective solvent) is −2·728 V. in methyl alcohol[323] and −2·657 V. in ethyl alcohol.[324] Koch[325] made measurements on cells of the type:

Na amalgam | NaI in pyridine, NaI in other solvent | Na amalgam

where 'other solvent' represents a variety of liquids including water. Taking the standard potential of sodium in water as −2·713 V. the following standard potentials (relative to $E^{\circ}_{\mathrm{H}_2} = 0$ in water) were derived for other solvents:-

Methyl alcohol	−2·551 V.	Acetone	−2·472 V.
Pyridine	−2·478 V.	Ethyl cyanoacetate	−2·408 V.
Ethyl alcohol	−2·477 V.	Propionitrile	−2·404 V.
Acetonitrile	−2·474 V.	Benzonitrile	−2·357 V.

In nitrobenzene the standard potential has been given as −2·545 V.,[326] and in ethyl bromide it is −2·45 V.[327] Other measurements of the sodium electrode potential have been made in liquid ammonia,[328–331] hydrazine[332] and formic acid.[333] The electrode potentials of the alkali metals in these last three solvents and in water have been compared in Table XII on page 47.

Relative values for the electrode potentials of sodium and other metals in various fused halide electrolytes have been obtained by direct measurement or by calculation from thermodynamic data, and electrochemical series have been developed.[313a, 333a–c] The order of the metals in the series varies with the anion and with the temperature, and in the case of mixed salts it may also be affected by complex formation. The difference in potential between sodium and the heavy metals decreases along the anion series: chloride, bromide, iodide.

Some measurements of the potential of sodium amalgam electrodes have been referred to above in arriving at the standard potential of sodium;[309,311,314,315] a number of other studies of sodium amalgam electrodes have also been made.[334–341] Many of the investigators have, however, worked only with a single, low, sodium concentration. Trümpler *et al.*,[314,341] using the glass membrane technique, made measurements at sodium concentrations between 0·0005 and 0·6%: the following potentials (on the hydrogen scale) are for amalgam electrodes at 25°C. in a sodium ion solution of unit activity:-[314]

% Na	0·0091	0·0138	0·0240	0·0352	0·0453
Amalgam Potential, (volts)	−1·770	−1·781	−1·797	−1·807	−1·815

% Na	0·0563	0·0865	0·1460	0·2579
Amalgam Potential, (volts)	−1·821	−1·835	−1·853	−1·876

Potentials obtained by the glass membrane technique have been found to be several millivolts more positive than those obtained by a direct method. Smith and Taylor,[311] using a direct method, obtained − 1·828 V. on the hydrogen scale for the potential at 25°C. of a 0·0651% sodium amalgam in a Na^+ ion solution of unit activity. Older direct measurements on amalgam electrodes in normal Na^+ ion solutions at 25°C., all made relative to a normal calomel electrode, have included −2·1430 V. for 0·1389% Na,[334] −2·1549 V. for 0·194% Na[337] and −2·1525 V. for 0·206% Na.[309] Bent and Swift,[315] from potential measurements on sodium amalgam concentration cells in non-aqueous media expressed the activity of sodium in dilute amalgams by the following equations:-

$$\begin{aligned}\log a/N\ (25^\circ\text{C.}) &= -12{\cdot}81441 + 15{\cdot}6130N + 7{\cdot}530\,N^2\\ \log a/N\ (15^\circ\text{C.}) &= -13{\cdot}32030 + 15{\cdot}87260N + 7{\cdot}110\,N^2\\ \log a/N\ (5^\circ\text{C.}) &= -13{\cdot}86807 + 16{\cdot}1820N + 5{\cdot}970\,N^2\end{aligned}$$

where a is the activity of sodium in the amalgam and N is its mole fraction. Combination of these three equations has given:-

$$\log a/N = \frac{-8387{\cdot}6}{T^{1{\cdot}138}} + \frac{338{\cdot}2\,N}{T^{0{\cdot}54}} + 7{\cdot}0\,N^2$$

Activities of sodium in solid amalgams have also been studied.[342] At concentrations up to about 0·1% of sodium, the potential of a sodium amalgam electrode gives approximately a linear plot against the logarithm of the sodium concentration, but at higher concentrations there is a deviation from this line.[341]

Measurements of the potential of amalgam cathodes during the deposition of sodium from concentrated sodium chloride solutions have been reported.[343-345]

The behaviour of sodium ions at the dropping mercury electrode was studied by Heyrovsky[346,347] in his first polarographic experiments; he gave the deposition potential of sodium at mercury from aqueous solutions as − 1·860 V. relative to a normal calomel electrode. Other more recent studies have been made in both aqueous and non-aqueous media. Despite the very negative standard potential of sodium, its ions are discharged at a mercury cathode in neutral and alkaline solutions without simultaneous discharge of hydrogen ions because of (*a*) compound formation between mercury and sodium reducing the discharge potential of the sodium ions, and (*b*) the high hydrogen overvoltage at mercury causing the discharge potential for hydrogen ions to be much higher than the reversible hydrogen potential. The negative potential does, however, limit the choice of supporting electrolyte; tetra-alkylammonium halides or hydroxides are virtually the only usable salts.[348] With tetramethylammonium chloride or hydroxide as the supporting electrolyte, the half-wave potential of sodium ions in aqueous solution is −2·15 V. relative to a normal calomel electrode.[349,350] More precise studies in a 0·1 M-tetramethylammonium hydroxide solution at 25°C. have given the half-wave potential as $-2{\cdot}142_5$ V. against a normal calomel electrode;[350a-b] the value extrapolated to zero concentration of the supporting electrolyte was the same within the limits of experimental error. Diffusion waves for sodium ions in alcohol–water mixtures are better developed than those in purely aqueous solutions.[351-353] In 50% ethyl alcohol at 25°C., with 0·1 M-tetraethylammonium hydroxide as the supporting electrolyte, the half-wave potential of sodium is −2·07 V. relative to a saturated calomel electrode: in 80% ethyl alcohol it is −2·035 V.[352,353] Sodium has a half-wave potential so close to those of potassium (−2·10 V.), rubidium (−1·99 V.) and cæsium (−2·05 V.) (all in 50% ethyl alcohol + 0·1 M-tetraethylammonium hydroxide) that these four elements cannot be differentiated polarographically.[348] In the presence of colloidal materials such as gelatin and agar agar the deposition potentials of the alkali metals at a dropping mercury cathode tend to become less negative.[354] Polarographic waves in ethylene glycol, trimethylene glycol, glycerol and in dioxan–water mixtures have also been studied.[351] At −36°C., in liquid ammonia saturated with tetrabutylammonium iodide as supporting electrolyte, the half-wave potential of the sodium ion relative to a 0·1 N-$Pb/Pb(NO_3)_2$ reference electrode is −1·31 V.[355]

Using an oscillographic method, Heyrovsky[356] has shown that when a dropping mercury electrode is subjected to alternate cathodic and anodic polarization at a frequency of 50 cycles per second, the cathodic and anodic depolarization processes occur at the same potential.

Ionization Potentials, Electron Affinity and Electronegativity

Ionization potentials of sodium have been calculated from spectral series limits. Values, in electron volts, from two recent compilations are:-

I	II	III	IV	V	VI	VII	VIII	IX	Reference
5·138	47·29	71·65	98·88	138·60	172·36	208·444	264·155	299·78	357
5·14	47·3	71·7	98·9	138·6	172·5	209·1	264·3	299·9	358

By extrapolation along the isoelectronic sequences, the tenth ionization potential of sodium has been estimated as 1460[358] and 1465 e.V.,[359] while the eleventh ionization potential has been estimated as 1646 e.V.[359]

Thermal ionization of sodium vapour occurs at high temperatures.[360–363] Ionization of sodium and other alkali metal vapours on hot surfaces of tungsten, molybdenum and other metals has attracted the attention of a number of workers.[364–371a]

Quadratic extrapolations from the ionization potentials of isoelectronic species have led to estimates of +0·08,[372] 0·0[373] and −0·08 e.V.[374] for the electron affinity of sodium: the last value is based on the latest spectroscopic data. It has been suggested[373] that electron affinities obtained by the above procedure are to be regarded as lower limits. A linear extrapolation method,[375] which in general yields less satisfactory values, has given +1·1 e.V. for the electron affinity. Hartree and Hartree,[376] using the consistent-field method, calculated wave functions for the negative Na^- ion and deduced that not only can this ion exist but also it is probably stable. A more recent and improved calculation of the electron affinity has given +1·2 e.V. confirming the stability of the Na ion.[377] Such ions have been reported from mass spectrometer studies.[378]

Sodium has a value of 0·9 on Pauling's electronegativity scale, values for the other alkali metals being Li, 1·0; K, 0·8; Rb, 0·8 and Cs, 0·7.[61] As pointed out by Mulliken,[379] the sum of the first ionization potential and the electron affinity when divided by 130 gives values in close agreement with Pauling's electronegativities for sodium and for other atoms.[61]

Optical and Photoelectric Properties

Thin films of the alkali metals are opaque to visible light, but they are highly transparent in the ultra-violet region of the spectrum.[380] The wave-length at which sodium ceases to exhibit the optical properties of a metal and acquires those of a transparent medium is about 2100 A.[380] No renewal of reflecting power in the far ultra-violet has been found down to 500 A.[381] A film of sodium on fluorite can be used as a filter to remove all visible and ultra-violet light of wave-length greater than 2100 A. and to pass the entire Schumann region of the spectrum.[382] In the transparent region, sodium yields plane polarized light by reflection of non-polarized light at an angle in accordance with Brewster's law.[380]

Ives and Briggs[383] studied the reflection of monochromatic plane polarized light from sodium surfaces, and from their results calculated the refractive index (n), the extinction coefficient for normal incidence (K_0), the reflecting power for normal incidence (R), the principal angle of incidence ($\bar{\phi}$) and the principal azimuth ($\bar{\psi}$). Values for these are given in Table XXI.

In an earlier measurement of the optical constants of sodium, Morgan,[384] using light of wave-length 5461 A., obtained 0·047 for the refractive index, 47·3 for the index of absorption and 96·9 for the reflecting power.

TABLE XXI. - OPTICAL CONSTANTS OF SODIUM

λ, (A.)	n	K_0	R (%)	$\bar{\phi}$	$\bar{\psi}$
5780	0·027	2·59	98·6	71° 4′	45° 16′
5461	0·029	2·32	98·2	69° 27′	45° 18′
4358	0·048	1·80	95·6	65° 41′	45° 26′
4047	0·048	1·56	94·5	63° 34′	45° 40′
3650	0·042	1·44	94·7	62° 21′	45° 36′
3126	0·040	1·02	92·6	57° 31′	45° 40′
2652	0·028	0·735	93·1	53° 34′	45° 29′
2536	0·026	0·621	92·7	51° 52′	45° 28′

A number of theoretical treatments of the optical properties of solid sodium have appeared, particular attention having been paid to the explanation of the transparency in the ultra-violet region.[385-391c] Zener,[386] using the free electron gas model, calculated the approximate values of the critical wave-lengths at which sodium and the other alkali metals become transparent to ultra-violet light.

Scattering of light from perfectly clean surfaces of liquid sodium has been studied.[392] The scattering is attributable to surface irregularities resulting from thermal agitation, and can be related to the surface tension of the liquid.

In the vicinity of the yellow D-lines (5890 A. and 5896 A.), sodium vapour exhibits 'anomalous' or selective dispersion. The variation of the refractive index with wave-length in the vicinity of these lines has been investigated by Stewart and Korff[393,394] who made measurements from 5830 A. to 5960 A. at several vapour densities. Fraser[395] was unable to detect any change in the refractive index of sodium vapour when measured with and without an applied magnetic field. Magnetic double refraction (Voigt effect) in the vapours of sodium and other alkali metal vapours has been studied by Gabler[396] who followed the variation of the effect with the vapour pressure of the metal.

Light falling on the surface of sodium liberates conduction electrons with an efficiency (expressed as:- number of electrons emitted/number of incident photons) that is dependent on the wave-length of the light and on the state of the sodium surface. For pure sodium films (deposited on aluminium) the efficiency has been found to be zero for light of wave-length greater than 5150 A. (having an equivalent photon energy of 2·4 e.V.).[397] From this threshold the efficiency increases steadily with decreasing wave-length to a maximum in the ultra-violet. For smooth (specular) surfaces prepared by rapid evaporation, the maximum, which has a value of $\sim 5 \times 10^{-4}$, is very flat and lies between 2000 and 3000 A.[398] Matt surfaces prepared by slow evaporation show a much sharper maximum of $\sim 4 \times 10^{-3}$ at a wave-length around 3000 A. These measurements are all for light at normal incidence: increasing the angle of incidence increases the maximum efficiency for both smooth and matt surfaces.[398] For smooth surfaces the efficiency with light at an angle of incidence of 60° is three or four times that at 0°, while for matt surfaces the efficiency at 70° is almost double that at 0°.[398]

Refs. p. 411

For very thin layers of sodium ($\lesssim$ 1 molecule thick) the substrate affects the observed photoelectric effect,[399] but for thicker layers the effect becomes characteristic of sodium, though the efficiency continues to increase with film thickness up to a limiting value reached at about 80 molecular layers.[397] This thickness is much greater than that for other alkali metals where the maximum sensitivity is reached with films of about 10 molecular layers. Thick sodium layers exposed to artificial mean noon sunlight have been reported to yield 0·095 to 0·44 microamp. per lumen.[400] Ives and Olpin[401] studied the variation of the photoelectric threshold for thin sodium films as a function of film thickness. With increasing thickness the threshold moved towards the red end of the spectrum, and after reaching an extreme position receded to the value for thick films. The wave-length of maximum excursion of the threshold into the red (~5900 A.) was found to be very similar to the wave-length of the first line of the principal series (5896 A.).

Burt,[402] who prepared a pure sodium surface by electrolysis through a soda-glass tungsten filament lamp immersed in fused sodium nitratemreported that the photoelectric efficiency to white light was largely independent of temperature between -190° and 20°C. Ives and Johnsrud[403] found little variation in the photoelectric efficiency over this temperature range when using white or blue light, but with yellow light the efficiency decreased considerably with decreasing temperature, the value at -180°C. being approximately 65% of that at 20°C. For white and blue light there was actually a very flat maximum in the efficiency-temperature curve at intermediate temperatures in the neighbourhood of -80°C.[403]

The presence of impurities in sodium surfaces usually increases the photoelectric threshold and causes the efficiency to show one or more pronounced maxima at visible or near ultra-violet wave-lengths (see Fig. 4). Both these effects lead to an increase in the efficiency to white light. This 'spectral selectivity' is also associated with 'polarization selectivity', the efficiency depending on the polarization of the light and usually being greatest when its E vector is in the plane of incidence.[404,405] Olpin[406] studied the effect of a large number of impurities on sodium photocells and found that those enhancing the sensitivity included air, oxygen, hydrogen, water vapour, sulphur vapour, sulphur dioxide, hydrogen sulphide, sodium bisulphite, carbon disulphide, methyl alcohol, acetic acid, benzene, nitrobenzene, acetone and some organic dyes such as tropæolin, eosin, cyanine, kryptocyanine, dicyanine and neocyanine. Deposition of a thin film of sodium on a sodium surface already treated with sulphur vapour resulted in a further twofold increase in sensitivity. An even greater.increase was brought about by admitting air to a sodium surface already treated with sulphur and then depositing a thin film of sodium on this. The sensitivity of the resultant NaS–air–Na surface extended to 10,000 A. Such treatments can produce cells with sensitivities as high as 7 microamp. per lumen for white light of colour temperature 2848°K.[406] The amounts of impurity required for sensitization are very small: the optimum amount of sulphur is $\sim 4 \times 10^{-7}$ g.cm.$^{-2}$,[407] and of oxygen $\sim 6 \times 10^{-7}$ g.cm.$^{-2}$.[408] Distillation of sodium in air at a pressure of several mm. of mercury results in a grey surface with a high photoelectric efficiency (Fig. 4).[409]

It has long been known[410] that the passage of an electric discharge through a low pressure of hydrogen in contact with an alkali metal results in an increase in the photoelectric sensitivity of the metal. More recent work has shown, however, that no sensitization occurs if the hydrogen is dried, and that helium plus water vapour are as effective as moist hydrogen.[411] It is quite possible that minute traces of some common impurity may be responsible for other sensitization processes among those cited above.

Absorption of light in sodium vapour from the series limit at 2412 A. to about 1600 A. has been studied by Ditchburn *et al.*[411a,b] The atomic absorption cross section at the limit was $11{\cdot}6 \times 10^{-20} \pm 1{\cdot}2 \times 10^{-20}$ cm.^{2} and it had a minimum value of $1{\cdot}3 \times 10^{-20} \pm 0{\cdot}06 \times 10^{-20}$ cm.^{2} at 1900 A. A theoretical treatment by Seaton[411 c] has reproduced the main features of the experimental results.

Miscellaneous Physical Properties

The chemical constant of sodium has been discussed by a number of authors.[155,173,186,412–414 a] From the vapour pressure measurements of several workers, Ladenburg and Thiele[155] gave the best value of the chemical constant as 0·78 ± 0·1. Other more recent calculations have given 0·83 ± 0·1.[414 a]

Empirical methods for the estimation of critical constants have given values of 1960°K. and 2550°K. for the critical temperature of sodium and 363 atm. and 300 atm. for the critical pressure.[203]

Independent measurements of the velocity of ultrasonic waves (12 Mc.) in liquid sodium at its melting point have given values of 2526 ± 5 m./sec. (temperature coefficient = −0·524 ± 0·003 m./sec./°C. between the melting point and 272°C.)[89] and 2395 ± 25 m./sec. (temperature coefficient = approximately −0·3 m./sec./°C. between the melting point and 235°C.).[90]

B. DISTILLED IN AIR AT A PRESSURE OF 1·5 MM. MERCURY

Studer and Williams,[415] using carefully purified sodium specimens, obtained −0·0021 for the Hall constant of sodium. More recently, Justi,[220] who made measurements from room temperature down to 0·73°K. and found the Hall constant to be substantially independent of temperature and field strength, has given the following values: −0·00127 at 20·4°K., −0·00124 at 78°K., and −0·00132 at 300°K. Calculated values of the Hall constant of sodium have included −0·00246[416] and −0·00245.[417]

Measurements of the contact potential difference between sodium and other surfaces have included the following values: sodium against molybdenum, 2·05 V.,[418] 2·0 V.;[419] tungsten, 2·2 V.;[419] iron, 1·4 V.;[419] nickel, 2·45 V.;[419] platinum, 2·1 V.,[419] 2·39 V.;[420] copper, 2·05 V.[419] When a tungsten filament is cleaned and exposed to sodium at a fixed pressure the work function falls to a minimum and then rises slowly to a final steady value.[421] The contact potential of the film of minimum work function against clean tungsten has been measured as 2·78 V.[421]

The photoelectric threshold for a clean sodium surface (see page 409) leads to a value of 2·4 e.V. for the work function. Theoretical values for the work function of sodium have included 2·15 e.V.[422] and 2·11 e.V.[423] From potential measurements on amalgam systems, Klein and Lange[424] obtained electron work functions for a large number of metals, their value for sodium being 1·60 e.V.

A method for detecting the level of liquid sodium in stainless steel tubes has been described.[425] It utilizes the change of inductance of a narrow coil of wire wound round the tube, and succeeds because the tube is only feebly magnetic and the liquid metal is a good conductor.

Sodium and its salts do not exhibit any natural radioactivity.[426-429]

PROPERTIES OF THE SODIUM ION

Some properties of the sodium ion, and some properties that relate to both the metal and its ion, have been dealt with under the appropriate sections above. Other properties of the Na^+ ion will be considered here.

The Ion in Solution

The heat and free energy of formation of the aqueous sodium ion at 25°C. are −57·279 and −62·589 kg.-cal.g.-ion^{-1} respectively.[1] The absolute heat capacity of the Na^+ ion at infinite dilution has been calculated from measurements on various aqueous salt solutions;[1a,b] assuming equal values for the heat capacities of the NH_4^+ and Cl^- ions, that of the Na^+ ion has been given as −15·0 g.-cal./degree/g.-ion.[1a] From thermal data for the three ioniza-processes, $NaCl\ (solid) \rightarrow Na^+\ (aq.) + Cl^-\ (aq.)$, $NaNO_3\ (solid) \rightarrow Na^+\ (aq.) + NO_3^-\ (aq.)$, and $Na\ (solid) + H^+\ (aq.) \rightarrow Na^+\ (aq.) + \frac{1}{2}H_2\ (g.)$, a mean value of 14·0 ± 0·4 g.-cal.g.-ion^{-1}degree^{-1} has been obtained for the entropy of the Na^+ ion (relative to that of the H^+ ion) in aqueous solution at 25°C.: individual values were 14·1 ± 0·5, 14·3 ± 0·5 and 13·7 ± 0·5 respectively.[2] The U.S. Bureau of Standards selected value[1] for the entropy of the aqueous sodium ion at 25°C. is 14·4 g.-cal.g.-ion^{-1}degree^{-1}.

After using a variety of methods to calculate the effective diameter of the hydrated sodium ion, Kielland[3] took a rounded value of $4{\cdot}5 \times 10^{-8}$ cm. for this dimension and then used the Debye–Hückel theory to compute activity coefficients of the sodium ion in aqueous solution at 25°C. The resulting values are shown in Table XXII.

TABLE XXII.- ACTIVITY COEFFICIENTS OF THE Na^+ ION IN AQUEOUS SOLUTION AT 25°C.

Total Ionic Concentration	0·001	0·002	0·005	0·01	0·02	0·05	0·1	0·2
Activity Coefficient	0·975	0·964	0·947	0·928	0·902	0·86	0·82	0·775

The discrepancy between the results of various experimental methods for determining ionic solvation numbers has been discussed by Bockris[4] who, as illustration, has given the following Table for the sodium ion:-

TABLE XXIII.- THE HYDRATION NUMBER OF THE SODIUM ION AT INFINITE DILUTION BY VARIOUS EXPERIMENTAL METHODS

Method	Hydration Number
Mobility[5]	4
Water Transport[6]	3
Mobility[7]	71
Dialysis[8]	17
Partial Molar Volume[9]	1
Polarimetric (0·5 N.)[10]	700 approx.*

* Estimated from the value 1111 for NaCl.

Bockris distinguishes between primary and secondary solvation (see page 56), and the methods that he considers probably give a measure of the former – viz. those employing ionic mobility, ionic entropy, compressibility and partial molar volume – yield values of 4, 4, 4 and 1 respectively for the hydration of the sodium ion. Using a dialysis method it has been reported that three water molecules are bound to the sodium ion forming a complex aquo-metal ion, and that a further five water molecules are bound as water of hydration of the aquo-metal ion.[11] Solvation of the sodium ion in other liquids such as methyl and ethyl alcohol, acetone, acetonitrile and benzonitrile has been studied.[12,13]

Independent treatments by Latimer and co-workers[14] and by Verwey[15] have led respectively to values of 94·6 and 94·5 kg.-cal.g.-ion^{-1} for the heat of hydration of the Na^+ ion, to 89·7 and 88·5 kg.-cal.g.-ion^{-1} for the free energy of hydration, and to 17 and 19·6 g.-cal.g.-ion^{-1}degree^{-1} for the entropy of hydration. Bernal and Fowler[16] in an earlier treatment in which two different methods were used, calculated values of 114 and 116 kg.-cal.g.-ion^{-1} for the heat of hydration of the Na^+ ion. A calculation by Webb[17] of the free energy of hydration gave 99 kg.-cal.g.-ion^{-1}. Miscenko[18] using thermochemical data on the solvation of salts has given the heat of solvation of the Na^+ ion in water as 98 kg.-cal.g.-ion^{-1}, in methyl alcohol as 100 kg.-cal.g.-ion^{-1}, and in ethyl alcohol as 99kg.-cal.g.-ion^{-1}. In separating the heats of hydration of salts into values for the individual ions Miscenko[18a] has rejected Bernal and Fowler's[16] basic assumption of approximately equal heats of hydration of the equi-radial K^+ and F^- ions, and has ascribed equal heats of hydration to the Cs^+ and I^- ions on the grounds that the difference in their radii is compensated by the dipole moment dissymmetry in the water molecule. From the Bjerrum equation for solvation the same author calculates values 169, 165 and 163 kg.-cal. g.-ion^{-1} for the heats of solvation of Na^+ in water, methyl alcohol and ethyl alcohol respectively; from the Born equation for solvation he calculates 171, 174 and 176kg.-cal.g.-ion^{-1} for the solvation energies in the same three solvents. A number of dubious assumptions are, however, involved in these calculations.[19]

Table XXIV shows values for the equivalent conductivity or mobility of the sodium ion at infinite dilution in water. These are taken from a recent compilation[20] of ionic mobilities that uses conductivity and transport number data from several sources.

TABLE XXIV. - MOBILITY OF THE SODIUM ION AT INFINITE DILUTION IN WATER

Temp., °C.	0	5	15	18	25	35	45	55	100
λ_∞	26·5	$30{\cdot}3_0$	$39{\cdot}7_7$	42·8	50·10	$61{\cdot}5_4$	$73{\cdot}7_3$	$86{\cdot}8_8$	145

The value at 100°C. is said to be reliable only within several units, while the values at 5°, 15°, 25°, 35° and 45°C. are significant to the first decimal place, and those at 0° and 18° to within two or three units in the first decimal place. In D_2O at 25°C. the mobility of the sodium ion at infinite dilution is 40·83;[21] in methyl alcohol at 25°C. it is 45·22.[22] While a considerable body of data exists for the conductivity of sodium salts in non-aqueous solvents, there is little corresponding transport data to permit calculation of precise ionic mobilities. Mobilities of the sodium ion in a variety of non-aqueous solvents have been obtained,[13,23] however, with the aid of such relationships as that between conductivity and viscosity (Walden's rule). The heat of transport[24] and entropy of transport[25] for the Na^+ ion have received attention.

Diffusion coefficients at infinite dilution may be obtained from the above mobility data using Nernst's limiting formula $D^\circ = RT\lambda_\infty/zF^2$. At 25°C. this leads to $1{\cdot}33 \times 10^{-5}$ cm.^{2}sec.$^{-1}$ for the self-diffusion coefficient of the sodium ion at infinite dilution in water. During recent years a number of studies of sodium self-diffusion have been made using radio-tracer techniques.[26-35] ^{22}Na - and sometimes ^{24}Na - has been used as the tracer isotope, and both diaphragm cell[26-28,30,34,35] and capillary tube[31-35] methods have been employed. In very dilute solutions the various methods have given fairly consistent results, but in higher concentration regions some wide differences have been observed.

A critical survey of the methods used in measuring ionic diffusion coefficients has been given by Mills and Adamson[34] who discuss also the disagreement between values obtained by the diaphragm cell and open-ended capillary methods. Higher values obtained with open-ended capillaries have been attributed in part to losses by mechanical convection. Using a new apparatus for measuring self-diffusion coefficients of Na^+ ions by means of open-ended capillaries, and by proper selection of the flow rate over the capillaries (1-3 mm./sec.), Mills[35] has obtained values over the concentration range 0·02 to 4 M. agreeing with those from diaphragm cells. These values are shown in Table XXV.

TABLE XXV. - SELF-DIFFUSION COEFFICIENTS OF $^{22}Na^+$ AT 25°C.

Na^+ conc. moles/litre	$D \times 10^5$ cm.^{2}/sec.	Na^+ conc. moles/litre	$D \times 10^5$ cm.^{2}/sec.
0·023	1·310 ± 0·005	0·981	1·251 ± 0·008
0·286	1·293 ± 0·004	2·270	1·104 ± 0·010
0·400	1·282 ± 0·008	4·373	0·905 ± 0·007
0·638	1·273 ± 0·010		

The temperature coefficient of the diffusion current of Na^+ ions at the dropping mercury electrode has been calculated by Ilkovic.[36]

Calculations of specific ionic viscosities have given a value of 0·0060 for the Na^+ ion in 0·1 N. aqueous solution.[37] Relationships between the viscosity, the mobility and the entropy of hydration of the sodium ion have been discussed.[38]

The extensive work of Okazaki on the Faraday effect in aqueous salt solutions has led to the following selection of values for the magnetorotivity of the sodium ion (in min.cm.^{2}gauss^{-1}g.-ion^{-1}), the magnetorotivity of the hydrogen ion being taken as zero:-[39]

Wave-length, A.	5900	5500	5100	4700	4300	3900	3500
$[M]$	0·17	0·17	0·21	0·27	0·36	0·48	0·60

Okazaki[40] has used $\Phi = Mnw\lambda^2/s(n^2 + 2)^2$, to define a molecular magnetorotation constant, where n and w are respectively the refractive index and Verdet's constant for light of wave-length λ, M is the molecular weight and s the density: the constant is the sum of the Φ values for the constituent ions. For the sodium ion, Φ has a value of $-0·23 \times 10^{-14}$. Values for other ions include: Li^+, -0·68; K^+, 0·61; Rb^+, 1·51; Cs^+, 3·35; H^+, -1·41; F^-, 1·57; Cl^-, 11·17; Br^-, 19·58 (all $\times 10^{-14}$).

The refractivity of the sodium ion in aqueous solution for the sodium D line is 0·20.[41]

As a result of the rapid progress in the development of new ion-exchangers during recent years, a great deal of work has been carried out on the exchange of sodium ions with other ions. Exchange equilibria and exchange rates for the system Na–H[42-66] have been studied widely for a variety of cationic exchangers - in particular resins of the sulphonic acid and carboxylic acid types. Other systems to receive attention include Na–K,[67-70] Na–Ca,[71-75] Na–Ba,[42,75,78] Na–Cu,[75,79] Na–Ag,[54,68,75,80,81] Na–Tl[68,75,81] and $Na–NH_4$.[82,84] The adsorbability of an ion is dependent on its charge and its hydrated radius, and for the alkali metals the order of the adsorption affinities or exchange affinities is $Cs^+ > Rb^+ > K^+ > Na^+ > Li^+$.[42,85] Self-diffusion of the Na^+ ion and other cations has been studied in various cationic exchangers.[60,86-92] Since ion-exchange is best dealt with from the viewpoint of the exchanger rather than from that of an individual ion it will receive no detailed treatment here: several specialist books may be consulted for further information on ion-exchange and its applications.[93–96]

The Gaseous Ion

Gaseous sodium ions may be generated by the normal methods used for producing ions, for example by the use of high speed charged particles or short wave-length radiations. The emission of sodium ions on heating various sodium salts in an electric field has been studied by Poirot.[97,98] A heated filament coated with a sodium compound mixed with an iron oxide catalyst has frequently been used as a source of sodium ions.[99–101]

At 0° and 298·16°K. the U.S. Bureau of Standards selected values for the heat of formation of the gaseous sodium ion are 144·534 and 146·015 kg.-cal. $g.\text{-}ion^{-1}$ respectively.[1]

The mobility of the Na^+ ion (in cm./sec./volt/cm.) in various gases at a pressure of 760 mm. Hg. and at 20°C. has been measured as follows:-[102,103]

Helium	23·1	Krypton	2·34
Neon	8·87	Hydrogen	13·6
Argon	3·21	Nitrogen	3·04

Later measurements in the rare gases (including xenon = 1·80 cm./sec./volt/cm.) are in close agreement with the above figures.[104] A study of the temperature variation of the mobility in helium between 92° and 477°K. has shown that the mobility increases with increase of temperature throughout this range.[105] Within 10^{-5} to 10^{-3} seconds of their liberation the mobility of Na^+ ions in hydrogen, nitrogen and helium is appreciably greater than (up to twice) that thereafter.[106–108,132] This has been attributed to the formation of ion clusters. Studies of the mobility of the Na^+ ion in all five rare gases containing small concentrations of water vapour have shown that the sodium ion acquires a cluster of water molecules which reduces its mobility by 30 to 50%.[104] In argon, krypton and xenon, an upper limit of six has been assigned to the number of water molecules in an ion cluster, but the true number is probably rather less than this. Other measurements have been made in pure water vapour.[109]

The ionization of inert gases by sodium and other alkali ions has been much studied.[101,110–119] Beeck and Mouzon[113–115] found that, in general, an inert gas is most easily ionized by the alkali metal nearest to it in the periodic classification: the potentials (ion velocities) required by Na^+ ions for them to ionize neon, argon, krypton and xenon were found to be 175, 105, 400 ± 10 and 300 ± 10 volts respectively. Later work by Varney;[101] who used a space-charge method sensitive to any resulting positive ions but unaffected by secondary electrons liberated from the walls, showed that sodium ions only produced ionization in neon (at 130 V.). It has been suggested[101] that the interference of secondary electrons may have been responsible for the results of Beeck and Mouzon. The excitation and ionization of mercury vapour by sodium ions has also been studied.[120–123] Mercury is ionized by sodium ions with energies of 88 ± 4 volts.[122]

Under the influence of an electric field, sodium ions may be carried from the gas phase into a glass diaphragm.[124,125] Migration through the diaphragm occurs and ions are displaced from its cathode side. Other gaseous ions may displace sodium ions from glass diaphragms under similar conditions.[124,125] Sodium ions can also migrate through quartz plates in a direction parallel to the principal crystallographic axis of the quartz.[126,126a]

The ionic refractivity of the gaseous sodium ion for the sodium *D*-line is 0·50.[41] Values for the polarizability of the sodium ion include $0{\cdot}21 \times 10^{24}$[127]

and $0{\cdot}17 \times 10^{-24}$.[126] Other dielectric parameters of the sodium ions have been evaluated.[129-131]

SOLUTIONS OF SODIUM AND SOLUBILITIES IN SODIUM

Solutions of Sodium in Liquid Ammonia

Sodium dissolves readily in liquid ammonia without reaction to give solutions that are deep blue when dilute and have a metallic, copper-like appearance when concentrated. Evaporation of the ammonia from freshly prepared solutions gives a residue of the original metal. Decomposition of the solutions is catalyzed by even minute traces of impurities. To obtain solutions of maximum stability, sodium is distilled into the preparation vessel under a vacuum of less than 10^{-3} mm. Hg., and sodium-dried ammonia is condensed on to it.[1] The vacuum system should be thoroughly outgassed, and carbon dioxide and mercury vapour should be rigorously excluded. In saturated solutions the number of ammonia molecules to each sodium atom is reported to be 5·48 at −33·8°C.[2] and 5·367 at −33·5°C.[3] Older measurements over a range of temperatures have shown that the solubility decreases slightly with rise of temperature.[4,5] Solution of sodium in liquid ammonia is an endothermic process, the heat of solution being approximately −1·4 kg.-cal./g.-atom in the neighbourhood of the boiling point of ammonia.[6,7] In the presence of dissolved salts the heat of solution is slightly different from that in the pure solvent.[7]

The rate of dissolution of sodium in liquid ammonia has been studied between −38·0° and −51·2°C.; it appears to be a diffusion-controlled process.[8] The solution rate is said to be increased by making the sodium cathodic and decreased by making it anodic.[8]

At low temperatures sodium solutions separate into two liquid phases. Kraus and Lucasse[9] examined the phase diagram down to −60°C. using the abrupt change in the electrical conductance to indicate the appearance of a second liquid phase on cooling solutions of various concentrations. The upper critical end-point of the system occurs at −41·6°C. and at a composition of 4·15 atom % of sodium. At −60°C., the two liquid phases contain 1·7 and 8·3 atom % of sodium. The phase curve differs considerably from that obtained previously by Ruff and Zedner.[10]

Dilute solutions of sodium in ammonia (~10^{-3} M.) are reported to darken noticeably and to suffer a change in the quality of the transmitted light on cooling from room temperature to −80°C.; the colour change is rapid and reversible with respect to temperature.[11] Measurements in solutions of sodium in ammonia at −60°C. have shown a single broad absorption band width with a maximum around 6800 cm.$^{-1}$ and a half-height width of about 3000 cm.$^{-1}$ [11a] A similar band is also shown by solutions of other metals in liquid ammonia.[11a]

A eutectic containing somewhat more than 13 atom % Na (~7 N.) is formed at −110°C.[12,13] Supercooling can, however, occur even with comparatively slow cooling. According to Birch and MacDonald[14] the solid phase consists of a non-homogeneous mixture of sodium and ammonia crystals, and a suggestion that a compound (possibly $Na(NH_3)_5$ or perhaps non-stoicheiometric) is formed[15] has been rejected. Ogg[16] has reported that rapid cooling of solutions of sodium in liquid ammonia to between −90° and −180°C. gives apparently homogeneous solid solutions. From dilute solutions the solid is blue and is visually identical with the corresponding liquid phase;[17] concentrated solutions have a bronze-like lustre.[16]

Sodium adsorbed on films of solid ammonia at −183°C. and at a pressure of 10^{-3} to 10^{-4} mm. Hg is reported to show the same colouration and optical absorption as in solutions.[18] Thin layers of ammonia containing small amounts of sodium, potassium, or lithium at 20°K. show an absorption band at about 1·15μ irrespective of the actual metal employed.[18a] There are further bands peculiar to the individual alkali metals: for sodium-ammonia layers at

TABLE XXVI. - DENSITY OF SOLUTIONS OF SODIUM IN LIQUID AMMONIA AT -33·8°C.

Moles NH_3/ Atom Na	5·48 (sat.)	6·73	8·87	11·03	13·10	17·41
Density	0·5782	0·5888	0·6044	0·6163	0·6251	0·6376
Moles NH_3/ Atom Na	21·07	27·26	37·84	48·04	55·17	64·14
Density	0·6494	0·6535	0·6603	0·6653	0·6681	0·6704

20°K. there is an absorption band at about 600 mμ.[18a]

The density of solutions of sodium in liquid ammonia is less than that of either of the constituents. Density values at -33·8°C. are given in Table XXVI.[2,19]

The volume expansion on solution has a maximum value of 43·14 c.c. per atom of sodium for a solution containing 11·2 moles of ammonia to each sodium atom; for a saturated solution it is 40·96 c.c. per g.-atom of sodium.[2] Other density measurements have been made for concentrations from zero up to saturation in the temperature ranges -75° to +33°C.[20] and -28° to +30°C.;[21] at 30°C. the density of a saturated solution is 0·5523.[21] Between -31·6° and -51·0°C. the density of a saturated solution varies almost linearly from 0·576 to 0·587.[22]

The coefficient of expansion decreases with increasing sodium concentration; values referred to 0°C. are:-[20]

Moles NH_3/Atom Na	5·48	6·82	11·22	21·5	69·0	103·0
$\alpha \times 10^3$	0·73	0·88	1·18	1·33	1·48	1·55

Adiabatic compressibilities of concentrated solutions of sodium in ammonia determined from sound-velocity measurements have shown a rapid increase in compressibility with increasing concentration.[22a] At 100 moles NH_3/g.atom Na the compressibility was 50×10^{-12} cm.^{2}/dyne: at 10 moles NH_3/g.atom Na it was 85×10^{-12} cm.^{2}/dyne.[22a]

Solutions of sodium in liquid ammonia have a lower viscosity than the pure solvent. Table XXVII gives viscosities in centipoises between -30° and +30°C. for sodium concentrations from zero to saturation.[23]

TABLE XXVII.- VISCOSITY (IN CENTIPOISES) OF SOLUTIONS OF SODIUM IN LIQUID AMMONIA

TABLE XXIX.- EQUIVALENT CONDUCTIVITY OF SOLUTIONS OF SODIUM IN LIQUID AMMONIA AT $-33{\cdot}5^\circ$C.

V	0·1081	0·1804	0·2768	0·5047	0·7861	1·038	6·305
Λ	545,600	484,700	296,200	82,490	12,350	3,228	554·7
V	13·86	30·40	65·60	318·6	3,479	17,260	37,880
Λ	478·3	478·5	540·3	773·4	988·6	1016·0	1034·0

A saturated solution boils at $-0{\cdot}2^\circ$C.[10]

The electrical conductivity of dilute solutions of sodium in ammonia varies in the same way as that of ordinary electrolytes, the equivalent conductivity approaching a limiting value at infinite dilution.[24] Working at $-33{\cdot}5^\circ$C., Kraus[24] found a minimum equivalent conductivity ($\sim$475) at a concentration of approximately 0·05 N.; thereafter the equivalent conductivity rose rapidly with increasing concentration. For the selection of values[3,24,25] given in Table XXIX. the 'dilutions', V, represent the number of litres of pure ammonia in which one gram atom of sodium is dissolved; the equivalent conductivity, Λ, is given as 1000 $V \times$ specific conductivity.

Other conductivity measurements by Gibson and Phipps[26] are in general agreement with those of Kraus. Measurements at $-33{\cdot}5^\circ$, $-48{\cdot}5^\circ$ and $-70{\cdot}0^\circ$C. showed, in each case, a minimum equivalent conductivity at a concentration of about 0·04 N. At these three temperatures the minimum equivalent conductivity values were 460, 360 and 235 respectively[24] (dilutions in litres of solution per g. atom Na). A saturated solution of sodium in ammonia at $-33{\cdot}5^\circ$C. has a specific conductance of $0{\cdot}5047 \times 10^4$ ohms^{-1}cm.$^{-1}$ which is approximately half the specific conductance of mercury at 0°C.; the atomic conductance of the saturated solution is $0{\cdot}672 \times 10^6$ reciprocal ohms.[3] In these concentrated solutions the conduction is metallic in character, and ammonia solutions of the alkali metals have been regarded as forming a link between electrolytic and metallic conductors.[24] (See below).

The temperature coefficient of conductance, $d\kappa/dT$, increases with increase of temperature.[26,27] Gibson and Phipps[26] found that the logarithmic coefficient $d \ln \kappa/dT$ had a value independent of temperature, *i.e.* the conductivity is an exponential function of temperature. At dilutions in the vicinity of 100 litres this logarithmic coefficient had a value of about 0·02. Kraus and Lucasse[28] have shown that the temperature coefficient is much greater in dilute solutions than in concentrated solutions. Near the saturation point they found a temperature coefficient of $\sim$0·066% per degree; the coefficient increased to a maximum value of $\sim$3·6% per degree at a dilution of 1·1 litre and thereafter decreased to 1·55% per degree at dilutions above 4 litres. A value of 2·25% per degree has been reported in more dilute solutions.[24]

In dilute ammonia solutions the conductivities of sodium and potassium, and of sodium and lithium, are practically additive, there being no evidence of compound formation between the metals.[29] Conductivity measurements have also been made on mixtures of sodium metal and sodium salts in liquid ammonia.[30] A study of the Wien effect in solutions of alkali metals in ammonia at -78°C. has shown that a 4% increase in conductivity occurs on applying an electrical field of about 15 kv./cm.[30a]

According to Kraus,[24,25] sodium atoms, sodium ions, free electrons and solvated electrons are present in equilibrium in ammonia solutions of sodium:-

$$\mathrm{Na} \rightleftharpoons \mathrm{Na}^+ + e^-$$
$$e^- + n\mathrm{NH_3} \rightleftharpoons e^-(\mathrm{NH_3})_n$$

In dilute solutions the electrons arising from the ionization of the sodium are solvated, and the decreasing degree of ionization with increasing sodium concentration results in a corresponding fall in the equivalent conductance. In more concentrated solutions some of the electrons become free from associated ammonia molecules, and the increased mobility of the negative carriers is made manifest by an increase in the conductance. At high sodium concentrations, the free electrons are responsible for the characteristic 'metallic' conduction. While this theory gives a satisfactory explanation of many facts, including the conductance behaviour, it meets difficulties when some other properties, - in particular, magnetic susceptibility - are considered.[31] Farkas[32] has given a quantum mechanical treatment of the electrical conduction in ammonia silutions of alkali metals in which it is assumed that the electrons are restrictedly free at all concentrations, and that conduction occurs by electrons undergoing 'non-mechanical' transitions from atom to atom in the direction of the field, the distance between the ordered array of atoms varying with the concentration. The theory leads to results in moderately good agreement with experiment for solutions containing one to five moles of sodium per litre of solution. More recently it has been proposed that the electrons are trapped in the solvent, these existing in the liquid cavities which serve to trap electrons either singly or in pairs.[32a,32b,61] This model which is compatible with a large body of experimental data has been discussed and elaborated by several authors.[11a,32c-32g]

Chittum and Hunt[33] have criticized the solvated electron theory and have maintained that alkali metals are dispersed in liquid ammonia as colloidal particles. In support of their theory they report that dilute solutions of sodium in ammonia display a Tyndall cone and that the blue colour of a sodium solution in ammonia cannot be made to pass through a membrane by electrodialysis. As a result of experiments with an ultramicroscope and an ultrafilter, Kruger[34] has also concluded that sodium-ammonia solutions are colloidal. Filtration removed the sodium and its associated blue colour, and resulted in a large increase in the electrical resistance of the solution. Other workers have criticized the method of preparation of the above 'colloidal' solutions, and deny that solutions of sodium in ammonia are colloidal in nature.[31,35]

Between 1945 and 1950 the question of superconductivity in solid sodium-ammonia solutions received considerable attention. But now that all the evidence can be examined, by far the greater part of it seems to point to the absence of such superconductivity in these solutions. Ogg[17] in 1945 observed a marked positive temperature coefficient of resistance in dilute solidified solutions (10^{-4} to 10^{-2}M) of sodium in ammonia at -80° to -100°C. in contrast to the negative coefficient for liquid solutions. Extremely rapid freezing of approximately molar solutions from -33° to -95°C. reduced the resistance by a factor of over 600.[16] Solid ring samples of sodium-ammonia, prepared by rapid freezing in a magnetic field, were found by Ogg to possess a magnetic moment which was taken to be indicative of a persistent current.[16] This report of superconductivity in sodium solutions at liquid air temperatures aroused considerable interest and led to much further investigation since all other known cases of superconductivity occur below about 10° to 14°K.[36,37] Other workers who have looked for persistent currents in ring samples or have made direct resistivity measurements have not, however, confirmed the existence of superconductivity in these solutions.[38-47] Ogg[48] in reply to such reports has considered that the solid cracks into a micro-mosaic pattern, and that it is a rare accident when the residual contact resistances are sufficiently small to allow an appreciable persistent current. He states that out of about 200 experiments performed by him only 7 gave a positive result. Several other workers have, however, carried out a considerable number of experiments with frozen rings with no positive results.[38,39,44,45] Hodgins[49] did observe small persistent currents - though much less pronounced than found by Ogg - in 4 out of 115

Refs. p. 435

experiments carried out with frozen rings, but in a later paper[50] in which he confirms his earlier observations of minute persistent currents, it is thought unlikely that these currents are due to superconductivity since their direction did not change with the direction of the magnetic field. MacDonald *et al.*[41] in their first experiments observed transient magnetic moments of the order of magnitude described by Hodgins, but these were traced to iron objects in the laboratory or to very small vibrations in the search coil: 85 experiments under more stringent conditions gave no positive results. Other studies have shown that there is a finite resistance in solid sodium–ammonia solutions at low temperatures,[47] and that the residual resistance is due to the solution itself and not to contact resistance.[38,46] At −183°C. the specific resistance of a saturated solution has been given as 5×10^{-4} ohm cm. compared with 2×10^{-4} ohm cm. at −33·5°C.[47] It has been demonstrated that the sharp decrease of resistance occurs just at the solidification point,[44] and that it occurs with slow as well as with rapid cooling;[46] the large change in resistivity has been attributed to the formation upon cooling of a bronze-coloured, sodium-rich phase.[46] A study has been made of the effect of rapid and slow freezing on the resistivity of a 2·1% solution of sodium in ammonia from −100° to −160°C.; with rapid freezing there is a maximum resistance at −114°C.[41] Suggestions have been advanced to account for the anomalies observed by Ogg other than by supposing the solid to be superconducting.[38,43]

The thermoelectric properties of solutions of sodium in liquid ammonia at −33°C. have been studied over the concentration range 0·002 **M.** to saturation.[1] The thermoelectric power increases with decreasing concentration over the whole range; in concentrated solutions its value is of the order of magnitude characteristic of typical metals.

In concentrated solutions sodium exhibits a weak paramagnetism; in dilute solutions it is strongly paramagnetic.[20,51] At intermediate concentrations (moles NH_3/Na = 50 to 100) the atomic susceptibility (χ_A) passes through a minimum, and at lower temperatures it in fact becomes negative.[20] Thus, for an ammonia/ sodium molecular ratio of 100 the atomic susceptibility at −60°C. is -28×10^{-6} and at −35°C. it is $+27 \times 10^{-6}$.[20] Figure 5 shows a plot of $\chi_A \times T$ against the logarithm of the molecular ratio NH_3/Na at −75°C. and at −35°C.[20] To explain these results, Huster[20] has assumed the existence of Na_2 molecules and the equilibrium:-

$$Na_2 \rightleftharpoons 2Na^+ + 2e^-$$

Freed and Thode[52] found that at 230°K. in 0·5 N. solution the atomic susceptibility was equal to that in the bulk metal; in 0·017 N. solution the atomic susceptibility exceeded that of the bulk metal by a factor of about 30 while in 0·0022 N. solution the factor was about 100. For very dilute solutions the susceptibility corresponds to a magnetic moment of 1 Bohr magneton per atom.[51] At −35° and −75°C. the volume susceptibility of solutions of sodium in ammonia has a substantially constant value ($\sim -0{\cdot}7 \times 10^{-6}$) independent of sodium concentration between 10^{-4} and 1 N.; at higher concentrations it falls rapidly.[20] Other measurements at 78° and 195°K. show a similar behaviour.[42] Prior to any of the above magnetic studies, a paramagnetism associated with sodium dissolved in ammonia had been observed by Taylor.[53]

Paramagnetic resonance absorption has been observed in ammonia solutions of sodium at low field strengths, and the signal amplitude has been found to be sensitive to the sodium concentration.[54,55,32f] The line width is very small, values as low as 0·02 gauss being recorded at the points of maximum slope.[32f] Resonance experiments performed at a frequency of 49 Mc./sec. in a precession field of 17·5 gauss and using a 0·1 M. sodium solution have shown an increase of signal amplitude with increasing temperature.[55]

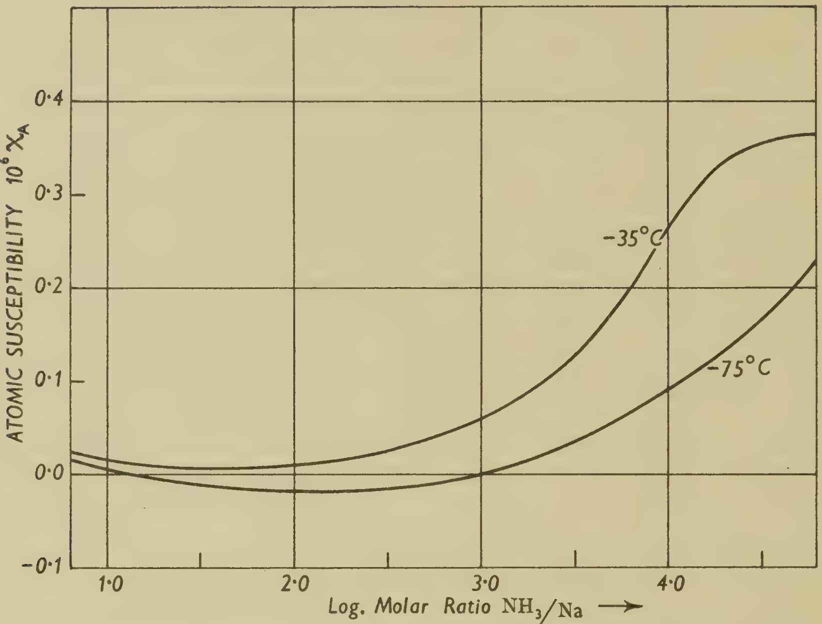

FIG. 5.- MAGNETIC SUSCEPTIBILITY OF SODIUM DISSOLVED IN AMMONIA

At lower sodium concentrations (0·001 M.) the effect was less marked.

A 0·033 M. solution of sodium in ammonia at -53°C. gave a half life of 37 seconds for the para-/ortho-hydrogen conversion.[56]

Solutions of sodium in liquid ammonia show photoelectric emission,[57-59] but there is no observable photovoltaic effect in the system.[60] The long-wave threshold for photoelectric emission changes from 7,700 A. for saturated solutions to about 15,000 A. for 0·0001 to 0·00001 M. sodium solutions.[58] For concentrated solutions, the spectral distribution of the quantum yield is similar to that for the solid metal.[57] At -78°C., concentrated solutions give a maximum response at 5,200 A.[59] For dilute solutions, the maximum sensitivity is in the near infra-red.[58] A marked increase in the electrical conductivity of very dilute solutions (10^{-5}M.) in the temperature range -35° to -75°C. has been observed upon irradiating with visible light.[61]

The solubility curve for mixtures of sodium and potassium in ammonia shows three branches corresponding to the solubility of pure sodium, the compound Na_2K, and pure potassium.[29] For mixtures of sodium and lithium, the curve is linear from pure sodium to pure lithium.[29] A study of the system Na-NaI-NH_3 at -33° to -31°C. has shown that dilute solutions of sodium in ammonia are miscible with salt solutions, but that concentrated solutions are not.[62]

Several reviews of the properties and constitution of metal-ammonia solutions have appeared.[37,63-65]

Decomposition of sodium-ammonia solutions and reactions of sodium dissolved in ammonia are discussed under 'Chemical Properties'.

Solutions of Sodium in its Salts

Sodium dissolves readily in fused sodium chloride, as little as 0·1% im-

TABLE XXX. - SOLUBILITY OF SODIUM IN SODIUM HALIDES

NaF		NaCl		NaBr		NaI	
T, °C.	Mole % Na	*T*, °C.	Mole % Na	*T*, °C.	Mole % Na	*T*, °C.	Mole % Na
979	0·19*	750	0·08*	650	0·04*	674	3·2
983	0·96*	790	0·15*	685	0·07*	722	4·1
1000	7·6	810	2·8	720	0·15	763	6·2
1001	15·8	826	4·9	750	4·6	810	8·3
1015	14·8	890	10·2	799	6·8	849	9·9
		929	21·3	852	7·3	909	14·9
		950	25·1	909	12·2	954	20·8
		976	32·0	950	~15·0		
		1001	33·0				

parting a deep red colour to the melt.[66] Higher concentrations of sodium give dark red to reddish-brown solutions. Slow crystallization of these solutions yields a blue product which dissolves in water with evolution of hydrogen. Lorenz and Winzer[66] gave the solubility in sodium chloride as 4·2% by weight at 800°C., and 15–20% at 850°C. These workers also made solubility measurements in sodium chloride–calcium chloride mixtures between 500° and 800°C. A recent study of the four binary sodium/sodium halide systems has given information concerning their phase diagrams at both high salt and high sodium concentrations.[67] From the trends in the portions of the curves studied it appeared that sodium would be completely miscible with each of its halides at temperatures above about 1000° to 1100°C. Table XXX gives a selection of the figures for the solubility of sodium in its halides; asterisked values are solubilities in the solid salt phase. In subsequent work[67a] the consolute temperatures and consolute mole fractions of sodium for each of the sodium/sodium halide systems were found to be as follows:

	Na/NaF	Na/NaCl	Na/NaBr	Na/NaI
Consolute Temperature, °C.	1182	1080	1025	1033
Consolute Mole Fraction Na	0·28	0·50	0·52	0·50

In each of the systems the dissolved sodium lowers the melting point of the pure salt by several degrees, and the eutectic temperatures and compositions are as follows:-

	NaF	NaCl	NaBr	NaI
m.p. of pure salt, °C. ± 0·5	995	803	747	661
Na/salt eutectic, °C.	990	794	740	656
Mole % Na in solid salt	~1	~0·2	~0·3	—
Mole % Na in liquid salt	~2	2·4	4·2	2·9
Mole % salt in liquid metal	17·0	2·3	3·4	1·4

Earlier electromotive force measurements in the system Na/NaBr indicated a much lower value of less than 1 mole % for the solubility of sodium in sodium bromide at about 850°C.[68] Table XXXI gives values for the solubility of sodium halides in liquid sodium: in the case of the asterisked figures the phase in equilibrium with the liquid metal is solid salt.[67]

From the temperature coefficients of solubility, the partial molar heats of solution of the solid salts in liquid sodium are: sodium fluoride, 26 ± 2 kg.-cal.; sodium chloride, 20 ± 3 kg.-cal.; sodium bromide, 24 ± 1 kg.-cal.; sodium iodide, 28 ± 2 kg.-cal. There is no evidence for the existence of solid compounds such as Na_2X in these systems.[67]

TABLE XXXI. - SOLUBILITY OF SODIUM HALIDES IN LIQUID SODIUM

NaF		NaCl		NaBr		NaI	
T, °C.	Mole % salt	*T*, °C.	Mole % salt	*T*, °C.	Mole % salt	*T*, °C.	Mole % salt
801	2·4*	550	0·12*	550	0·21*	550	0·06*

983	16·4*	832	4·2	757	3·3	699	1·5
1004	17·3	874	5·8	825	4·6	800	2·8
1048	20·0	913	8·3	894	7·8	882	5·7
1078	23·6	957	11·1	955	12·1	959	10·5

Electrical conductivity measurements have been made in the systems sodium/sodium chloride and sodium/sodium bromide.[68a] Specific conductance increases continuously with metal concentration but equivalent conductance shows a more complex concentration dependence.

Additive colouration of alkali halide crystals by contact with liquid sodium or sodium vapour is discussed on page 389.

Early work[69] gave figures for the solubility of sodium in fused sodium hydroxide, and regarded it as a case of simple solution; but it has since been shown that chemical change may occur in this system.[70-72] A blue colour has been reported for solutions of sodium in caustic soda.[73]

Other Solutions of Sodium

Moissan[74] in 1899 reported that sodium dissolves in methylamine, and other later workers[26,75] have also reported a slight or moderate solubility. Recent work has shown, however, that purified methylamine, practically free from water and ammonia, dissolves sodium at temperatures below 0°C. only after several hours, to give a solution of low sodium concentration.[76] The slight solubility is attributable to residual contamination by ammonia.[76] The absorption spectrum of the blue solutions in methylamine has been studied,[11a,75,76] as has that in ammonia/methylamine and ammonia/ethylamine mixtures.[11a] Sodium is reported to be soluble in ethylenediamine,[65] but it is insoluble in ethylamine[77,78] and in secondary and tertiary amines.[77]

Solubilities in Sodium

The use of liquid sodium as a heat transfer agent has led to work on the solubility of a number of impurities in the metal. Oxygen-containing impurities are of considerable practical importance since the presence of oxygen results in increased corrosion of containers, and the corrosion products adversely affect heat transfer coefficients. Also precipitation of sodium oxide in the cooler parts of the system can produce blockages. Values for the solubility of sodium monoxide in sodium tend to be rather variable: Fig. 6 shows results obtained in three American laboratories.[79,80]

Sodium hydroxide is soluble in liquid sodium to the extent of ~0·02% at 350°C.[79,80] The solubilities of sodium hydride and sodium carbonate in liquid sodium are given in Tables XXXII and XXXIII.[81] The presence of these two impurities can lead to errors in the analysis for oxygen in sodium by the amalgamation method.[81]

Barium oxide has a solubility of less than 0·05 wt.% in sodium at 500°C.[82]

Figures for the solubility of sodium halides in the metal at temperatures greater than 550°C. have been given above (Table XXXI). At 400°C. the solubility of sodium chloride in liquid sodium is reported to be considerably

ATOMIC WEIGHT AND ISOTOPES

Until 1953 the value for the atomic weight of sodium accepted by the International Commission on Atomic Weights had for many years remained at 22·997, a value that derived from determinations of the sodium chloride : silver, and sodium chloride : silver chloride ratios by Richards and Wells[1] in 1905. An accumulation of evidence, mainly from mass spectrometric measurements and nuclear calculations (**see page 438**), indicated that this value was too high and finally led to the adoption in 1953 of the lower value 22·991.[2]

For elements such as sodium that have no natural isotopes (see page 438), the accuracy and relative ease associated with determinations of the masses of single nuclear species by physical methods (mass spectrometry and nuclear energy calculations) have now resulted in these more recent methods completely displacing chemical methods for the determination of atomic weight. A few chemical determinations of the atomic weight of sodium have, however, been made during the last thirty years or so.[3-5]

Johnson,[4] in 1933, prepared pure sodium chloride by precipitating the salt by means of hydrogen chloride from a saturated solution and then crystallizing it from water: each stage was carried out three times. A weighed quantity of the fused salt was dissolved in water and used to precipitate silver chloride from an approximately equivalent amount of silver nitrate solution prepared from a weighed quantity of pure silver. After standing for some time, a portion of the supernatant liquid was withdrawn, filtered and analysed nephelometrically or potentiometrically for excess silver or chloride. Preliminary analyses enabled the silver and chloride contents of the solutions to be adjusted more closely to exact equivalence either by modifying the starting amounts of sodium chloride and silver or by making additions of dilute standard silver nitrate or sodium chloride solution. The end point was usually determined by a number of sets of analyses over a period of several days. In other experiments the precipitated silver chloride was collected quantitatively. Taking Cl = 35·457 and Ag = 107·880 (still their accepted values), the atomic weight of sodium obtained from both sets of experiments was 22·994.

In 1934 Baxter and Hale[5] obtained a value of 3·14950 for the ratio I_2O_5 : Na_2CO_3. They used carefully purified iodine pentoxide and sodium carbonate, and the end point for the reaction between these substances was determined with bromothymol-blue after carbon dioxide had been expelled. Uncertainties at that time in the atomic weights of carbon and iodine prevented calculation of an unequivocal atomic weight for sodium. When 1953 values are taken for carbon and iodine the above ratio gives 22·991 for the atomic weight of sodium.

Earlier values for the Na_2CO_3 : 2Ag[6] Na_2CO_3 : 2AgBr[6] Na_2CO_3 : Na_2SO_4[6] and Na_2CO_3 : I_2O_5[5] ratios, reconsidered in the light of a then new value (12·010)[7] for the atomic weight of carbon, led Scott and Hurley[8] to suggest in 1937 that the value of 22·997 for the atomic weight of sodium was 0·003 to 0·004 units too high.

From density and *X*-ray data for solid sodium chloride, values of 22·980,[9] 22·996[10,10a] and 22·997[11] have been reported for the atomic mass of sodium.

In his classical work with the mass spectrograph, Aston[12,13] showed that sodium was a simple element with but one isotope of mass number 23. Later work by Bainbridge[14] showed that if ^{21}Na, ^{22}Na or ^{25}Na exists it does so to the extent of less than one part in 3000, 800 and 3000 respectively of ^{23}Na. In 1936, mass spectrographic evidence[15] was reported for the existence of ^{22}Na with a $^{23}Na/^{22}Na$ ratio of 5000 ± 500, while the upper limits for ^{20}Na, ^{21}Na, ^{24}Na and ^{25}Na were set at 1 part in 50,000 of ^{23}Na. A later careful search for ^{22}Na has not, however, confirmed the natural existence of this isotope and the upper limit for its abundance has been given as 1 part in 30,000 of ^{23}Na.[16]

Several sodium isotopes with short half lives have been produced artificially by nuclear reactions. A recent review which also summarizes methods of production and disintegration schemes lists the following:[17]

Isotope	Approx. Half Life
^{20}Na	0·3 sec.
^{21}Na	23 sec.
^{22}Na	2·7 yrs.
^{24}Na	15 hours
^{25}Na	60 sec.

Mass spectrometric measurements[18] have given a value of 22·99665 ± 0·00008 for the mass of ^{23}Na. This and the following atomic masses are all on the physical scale (^{16}O = 16). From the energies of a series of three reactions by which ^{23}Na is converted into ^{16}O, Way[19] calculated a value of 22·9971 for the mass of the ^{23}Na atom. By combining two reactions starting with ^{22}Ne he obtained ^{23}Na = 22·9972, and a series of three steps from aluminium to sodium gave ^{23}Na = 22·9968. Other values for the mass of ^{23}Na derived from nuclear reaction energies are 22·997055 ± 0·000025[20] and

22·9972.[21] The above six physical determinations lead to an average value of 22·9970 for the mass of ^{23}Na. Since sodium is a simple element this value can be converted directly to the chemical scale to give the atomic weight of sodium. Such conversion (factor = 1·000275) yields an atomic weight of 22·9907. As discussed above (see page 437), this value provides the main basis for the adoption of Na = 22·991 as the International Atomic Weight.

Masses obtained from nuclear calculations for artificial sodium isotopes[20] include ^{21}Na = 21·004286 ± 0·000039, ^{22}Na = 22·001409 ± 0·000025 and ^{24}Na = 23·998568 ± 0·000026, all on the physical scale.

SECTION XXV

THE CHEMICAL PROPERTIES OF SODIUM

By (MRS.) F. DICKINSON

A freshly cut surface of sodium, viewed in the dark, emits a greenish light, the intensity of which increases as the temperature is raised. The chemiluminescence consists of a narrow band with a maximum at about 5000 A. believed to be due to the rupture of the hydrogen-oxygen bond in water vapour, resulting in the formation of sodium hydroxide.[1-3] An electron diffraction study of the surface of sodium after exposure for five minutes to air or air containing water vapour has shown that in the first case sodium hydroxide crystals of grain size 10^3 A. are arranged at random on the metal surface, and in the second case larger, oriented sodium hydroxide crystals are present.[4] Carbon dioxide in the air converts some of the hydroxide to sodium bicarbonate.[5-7]

Liquid sodium ignites in air at about 125°C. and burns quietly in a comparatively dry atmosphere giving off dense, white, caustic smoke. The temperature of the burning mass increases rapidly to 833°-889°C. In this condition it spalls concrete, consumes asbestos, fire-brick and similar materials and reacts with glass. It also reacts violently with common fire extinguishers such as water, carbon dioxide snow and carbon tetrachloride.

Liquid sodium fires can be safely extinguished with dry sodium carbonate, and blanketed with nitrogen.[8,9]

Dry oxygen forms a grey coating on a freshly cut surface of sodium and the reaction quickly ceases if moisture is not present to remove the protective film. Whereas some workers have stated that the reaction is accompanied by luminescence[10] others have found that no luminescence occurs if the oxygen is freed from moisture.[2,3] The rate of oxidation at a surface of sodium at room temperature depends markedly on the presence of a small amount of inert gas. With pure oxygen the rate is very low and a white layer of sodium monoxide is formed. With a small amount of nitrogen the rate is very high and coloured films of oxide are formed. If the oxygen pressure is raised the rate is suddenly lowered; heating to about 90° C. results in a fast reaction rate.[11]

More recently the oxidation rate of sodium at -79°, -20°, 25°, 35° and 48°C. has been studied by Cathcart, Hall and Smith. In dry oxygen the rate is found to be small and the oxide film highly protective. A slight increase in the rate of oxidation which occurs at 48° C. after 25,000 to 30,000 minutes has not been explained.[12]

An early literature reference states that sodium can be distilled in very dry oxygen.[13]

The production of sodium monoxide is brought about by treating sodium amalgam with oxygen; a mixture of sodium monoxide and peroxide is first formed and the peroxide is then reduced by sodium amalgam to the monoxide.[14]

When about 0·5g. of sodium is heated gently in a porcelain dish, it melts and spreads owing to the lowering of its surface tension; the metal is coated with a blue skin, which phosphoresces in the dark, and on cautious treatment with water the reaction product gives off oxygen. Treatment with dilute sulphuric acid yields hydrogen peroxide which turns starch-iodide paper blue. These simple experiments demonstrate the ease with which sodium is converted to sodium peroxide.[15]

Sodium peroxide may be formed in two stages: oxidation of the metal in dry air to form the monoxide, followed by oxidation with 90% oxygen to yield sodium peroxide.[16] Sodium peroxide is also formed by the rapid oxidation of sodium in liquid ammonia, see page 509.

The rate of oxidation of sodium may be controlled by allowing a mixture of the metal and an inert material, such as 10% of sodium and 90% of sodium monoxide, both in finely divided form, to react with oxygen to form additional sodium monoxide or peroxide, more sodium being added as required.[17]

A superficial layer of sodium monoxide on particles of sodium peroxide is obtained by mixing together sodium and sodium peroxide in an inert atmosphere at a temperature above the melting point of sodium but below the reaction temperature, in order to form a film of sodium on the peroxide particles, and then raising the temperature to that required for the reaction.[18]

The production of sodium monoxide and peroxide from molten sodium and sodium peroxide, and arrangements for continuous operation, have been described.[19-21] In the manufacture of alkali peroxides the molten alkali metals are atomized in spray guns. An oxidizing atmosphere is used to cause the formation of peroxides. The peroxide is cooled quickly by the flow of air so that the temperature is reduced below the fusion temperature of the oxide. A considerable excess of air is necessary, and since sodium is less reactive than potassium, the former must be atomized to a more minute degree.[22,23] Sodium amalgams on exposure to air are not peroxidized as observed by Rinck *et al.*,[24] even at 60°C. and with a larger contact area. When, however, 0·035–0·50 mole fraction of potassium is added to the sodium and amalgamated, potassium superoxide, which is readily formed, catalyzes the formation of sodium peroxide. No oxidation of mercury to the oxide Hg_2O occurs as is found in the peroxidation of potassium amalgams in the absence of sodium.[25] According to Feldmann,[26] sodium amalgam containing 0·264% of sodium reacts with oxygen at 10 atm. pressure at room temperature to give a quantitative yield of sodium peroxide, but when the reaction mixture is allowed to stand, all of the peroxide ultimately disappears and the mercury is oxidized. If the reaction is carried out at 100°C. the oxide HgO is immediately formed and only a trace of sodium peroxide is produced. In this case sodium acts as a catalyst because mercury is not oxidized under these conditions in the absence of sodium. If sodium amalgam is agitated with oxygen at room temperature, the amalgam becomes pasty owing to the formation of sodium peroxide, but the reaction is inhibited by the presence of water. Decomposition with sulphuric acid of sodium peroxide formed by the oxidation of sodium amalgam does not give a good yield of hydrogen peroxide and with 20% sulphuric acid at −1°C. a concentration of only 0·5% hydrogen peroxide is obtained. Lower temperatures and other acids such as phosphoric acid are no better. It is also difficult to separate sodium peroxide from mercury either by centrifuging or by distillation under reduced pressure. When a 0·1% sodium amalgam is vigorously agitated with oxygen so that the amalgam surface is continuously destroyed, a 98·7% yield of sodium peroxide is obtained in 41 minutes at 20°C. The product is filtered on a glass suction filter.[27] The peroxide undergoes a secondary reaction on standing, giving varying amounts of sodium monoxide.[28]

Examples are given in a patent specification for the production of sodium peroxide and other compounds by treating sodium amalgam with a gaseous reactant, oxygen in the case of sodium peroxide, under water-free conditions.[29]

The production of sodium peroxide from sodium amalgam and the economic aspect of the production of sodium peroxide by the process described above have been reviewed by Nicolai.[30] When this process is carried out in the presence of water, hydrogen peroxide is formed: $2Na + O_2 + 2H_2O \rightarrow H_2O_2 + 2NaOH$.

Refs. p. 501

Sodium superoxide, NaO_2, is prepared by heating metallic sodium at 300° C. with oxygen at a pressure of 2700 lb. per sq. in. The product obtained evolves oxygen on contact with moisture equivalent to a 70% conversion to sodium superoxide. The best conversions are obtained when sodium peroxide, of low bulk density and a high surface area, prepared by the atomization of molten metallic sodium according to the patent specification,[23] is heated in a bomb at a temperature of at least 200° C. in contact with oxygen at a pressure of at least 1500 lb. per sq. in. A product of low available oxygen content results if the peroxide is dense or in the form of hard granules.[31]

Sodium superoxide, NaO_2, and sodium peroxide, Na_2O_2 are reduced by molten sodium at 500° C. to sodium monoxide, Na_2O.[32]

Sodium superoxide is formed by the rapid oxidation of sodium in liquid ammonia at −77° C. (see page 509).

The following values are given for the heat of formation of sodium monoxide, expressed as kg.-cal./g.mole:-

$$2Na(c) + 0\cdot5O_2(g) \rightarrow Na_2O(c), \Delta H^\circ_{298} = -100\cdot7;^{33}$$
$$-99\cdot4;^{34} \quad \Delta H^\circ_{293} = -102\cdot87 \pm 0\cdot32.^{35}$$

The free energy expressed as kg.-cal./g.mole is given as, $\Delta F^\circ_{298} = -91\cdot4$;[33] $-90\cdot0$.[34] Under the following conditions:-

$$2Na(l) + 0\cdot5O_2(g) \rightarrow Na_2O(c), \Delta H^\circ_{400} = -104\cdot20$$

and $\Delta H^\circ_{500} = -104\cdot21$.[33]

For sodium peroxide: $2Na(c) + O_2(g) \rightarrow Na_2O_2(c), \Delta H^\circ_{298} = -120\cdot6$,[33 34] and at about 20° C., $\Delta H^\circ = -124\cdot84 \pm 0\cdot32$.[35]

Gilles and Margrave give a value of $-122\cdot1 \pm 1\cdot2$ kg.-cal./g.mole for the heat of formation of sodium peroxide at 298° K.[36]

For the heat of formation of sodium superoxide:-

$$Na(c) + O_2(g) \rightarrow NaO_2(c), \Delta H^\circ_{298} = -61\cdot9 \text{ kg.-cal./g.mole}^{33,34}$$

Gilles and Margrave give $-62\cdot1 \pm 0\cdot7$ kg.-cal./g.mole for the heat of formation of sodium superoxide at 298° K.[36]

It is unlikely that sodium peroxide or superoxide is stable in the presence of liquid sodium.[33]

Haber and Zisch have observed the formation of a small cone-shaped flame when nitrogen, laden with sodium vapour at atmospheric pressure and at a temperature below which black-body radiation would be visible, *i.e.* below 525° C., enters a space containing oxygen.[37]

The reaction of sodium vapour with oxygen has been studied kinetically by the method developed by Hartel and Polanyi[38] for the determination of rates of slow atomic reactions. Sodium vapour at an initial pressure (pNa) is introduced with an inert gas through a nozzle where it comes in contact with oxygen. The distance to which the sodium vapour penetrates is determined by means of a sodium resonance lamp. Surface reactions are minimized by introducing the reactants in an inert gas stream, the rate of diffusion of sodium in nitrogen being such that the sodium vapour leaving the nozzle is used up before it reaches the walls of the vessel. This largely avoids the difficulties involved when a solid deposit is formed. The procedure is described as the 'diffusion flame' method because the reaction is also accompanied by a luminescence. If pNa and po are the pressures of sodium at the centre and edge of the flame respectively, R the radius of the flame, and r that of the nozzle, δ the diffusion coefficient of sodium in nitrogen, px the pressure of oxygen in the reaction vessel and T the absolute temperature, then the velocity constant for the reaction is given by:-

$$k = \frac{(\ln p\mathrm{Na}/p\mathrm{o} - \ln R/r)^2}{(R - r)^2} \cdot \frac{\delta}{p\mathrm{x}} \cdot \frac{1}{T}$$

Under the conditions of their experiments, using sodium vapour at 0·0016mm. pressure, argon, helium or nitrogen at 2–10mm., oxygen at 0·02–0·38mm. and a reaction temperature of 250°C., Haber and Sachsse[39] have found that the reaction velocity constant varies almost linearly with the pressure of the inert carrier gas. A termolecular reaction occurs: $Na + O_2 + X \rightarrow NaO_2 + X$ (where X = He, A or N_2), the inert gas acting as a 'third' body, and carrying away the energy of the reaction, followed by: $NaO_2 + Na \rightarrow 2NaO$, finally giving a deposit of sodium peroxide on the walls of the vessel. The reactions, $2Na + O_2 \rightarrow 2NaO$ and $Na + O_2 \rightarrow NaO + O$ do not occur to any appreciable extent. The electrical conductivity of the gas mixture does not increase as a result of the oxidation.

Bawn and Evans have studied the above reactions over a wider range of carrier-gas pressures, the experimental method being that of Hartel and Polanyi with the improvements recommended by Heller.[40] Their results are given in Table I.

TABLE I. - REACTION OF SODIUM VAPOUR WITH OXYGEN AT 260°C.

Pressure of Na at nozzle mm. × 10^3	Rate of flow of N_2 mol./sec. 10^8	Rate of flow of O_2 mol./sec. 10^8	Total pressure in reaction vessel mm.	Partial pressure of O_2 mm.	Diffusion coefficient of Na mol./cm.^{2}/sec.	Radius of flame cm.	Velocity constant k c.c.mol.$^{-1}$sec.$^{-1}$
1·64	3196	28·08	5·46	0·048	93·06	1·75	$2{\cdot}55.10^{11}$
1·64	3220	5·02	10·21	0·016	49·78	1·75	$4{\cdot}08.10^{11}$
1·64	3174	4·55	10·82	0·016	46·97	1·75	$3{\cdot}95.10^{11}$
1·64	3227	1·38	16·20	0·007	31·37	1·75	$5{\cdot}90.10^{11}$
1·64	3270	0·49	24·00	0·004	21·18	1·75	$7{\cdot}64.10^{11}$

Bawn and Evans confirm that at low nitrogen pressures a termolecular reaction occurs and that the velocity constant varies linearly with the inert gas pressure. An associated complex molecule, NaO_2^*, which carries the heat of reaction as internal energy, is first formed: $Na + O_2 \rightarrow NaO_2^*$; the lifetime of this complex is probably about 10^{-9} seconds and it may dissociate thus: $NaO_2^* \rightarrow Na + O_2$ or be stabilized by subsequent collision with a nitrogen molecule: $NaO_2^* + N_2 \rightarrow NaO_2 + N_2$, the nitrogen carrying away the energy of the reaction. At higher inert gas pressures the reaction changes over to a simple bimolecular reaction. In the following equations, A and B are the reactants, C is the 'third' body, nitrogen, and k_1, k_2, k_3 the individual velocity constants: $A + B \rightarrow AB^*(k_1)$; $AB^* \rightarrow A + B(k_2)$; $AB^* + C \rightarrow AB + C^*(k_3)$; $k_1(A)(B) - k_2(AB^*) - k_3(AB^*)(C) = 0$. The measured rate of reaction, $d(AB)/dt = k_3(AB^*)(C) = k_1(A)(B) - k_2(AB^*)$. When the pressure of C is high,

k_2 is small and $d(AB)/dt = k_1(A)(B)$ *i.e.* the reaction is bimolecular; and these conditions have been realized by Bawn and Evans.[41]

From a study of the vapour pressure of sodium monoxide, Brewer and Margrave have shown that the vapour consists predominantly of sodium atoms and oxygen molecules. At 1350°K. a mixture of sodium and oxygen gases at 1mm. pressure is calculated to be thermodynamically stable while a mixture at 1atm. pressure is stable above 2100°K. and should not undergo reaction.[42] Theoretical calculations of the stability of solid and gaseous alkali oxides indicate that at 1000°K. all the gaseous alkali oxides except lithium monoxide are unstable with respect to dissociation.[43]

In a limited amount of water, e.g. when small particles of sodium adhere to the sides of a beaker above the water level, a blue coloration is observed owing to the solution of the metal in water. No such colour is produced when sodium is rubbed on ice.[44] Sodium begins to react with ice at −98°C.; with water the reaction is vigorous and may be explosively so when large surfaces are involved.

The sodium-water reaction may be expressed by either or both of the following equations: $2Na + H_2O \rightarrow Na_2O + H_2 + 31{\cdot}08$ kg.-cal. per mole at 25°C.; $Na + H_2O \rightarrow NaOH + 0{\cdot}5H_2 + 33{\cdot}67$ kg.-cal. per mole at 25°C. The reaction will proceed to give sodium hydroxide and hydrogen as long as the temperature is below the melting point of sodium hydroxide, even if excess sodium is present. If, however, the temperature is raised above this value, sodium hydroxide will react with additional sodium to form sodium monoxide and hydrogen.[33]

Thermodynamic data for the reaction of steam on liquid sodium are as follows: $Na(l) + HOH(g) \rightarrow NaOH(c) + 0{\cdot}5H_2(g)$; $\Delta H^\circ_{298} = -45{\cdot}7$ kg.-cal./mole; $\Delta H^\circ_{400} = -45{\cdot}56$; $\Delta H^\circ_{500} = -44{\cdot}87$; $\Delta F^\circ_{298} = -37{\cdot}4$ kg.-cal./mole; $\Delta F^\circ_{400} = -34{\cdot}00$; $\Delta F^\circ_{500} = -28{\cdot}91$.[33]

The heat of reaction of sodium with an infinite quantity of water at 25°C. has been determined by Ketchen and Wallace as −44·35 ± 0·7 kg.-cal. per g.-atom of sodium. The heat of formation of aqueous sodium hydroxide, calculated from the above result, is −112·37 kg.-cal.[45,46] Roth and Kaule's value of −45·27 ± 0·15 kg.-cal. per g. atom of sodium at 22·4°C. and 4510 moles of water per mole of sodium hydroxide gives the heat of formation of aqueous sodium hydroxide as −113·62 ± 0·15 kg.-cal. at about 20°C.[35] The value of 44·78 ± 2·10 kg.-cal. per g. atom of sodium at 25°C. obtained by Hagen and Seiverts[47] for the reaction of sodium with an infinite quantity of water is much nearer the later figure of Ketchen and Wallace, who consider the result of Roth and Kaule too high on account of experimental error. Still more recently Messer, Ludwig and Fasolino have measured the heat of hydrolysis corrected to infinite dilution and 25°C. for the reaction: $Na(s) + H_2O(l) = NaOH(\infty) + 0{\cdot}5H_2(g)$ and found it to be: −44·23 ± 0·13 kg.-cal. per mole.[48]

For all practical purposes the reaction between sodium and water cannot be reversed; to do so would require hydrogen pressures of the order of 10^{50} atm. The estimated final isothermal and adiabatic pressures and adiabatic temperatures which would result, when 23g. of sodium is allowed to react with 2–6000g. of water at an initial temperature of 18°C. and pressure of one atm. in a rigid container, in which the hydrogen evolved must occupy the volume created by the difference between the amounts of reactants and the reaction products, are shown in Fig. 1.[33]

The reactions resulting from a leakage of water in heat transfer systems where sodium is the heat-transfer agent, have been evaluated from studies conducted at the Knolls Atomic Power Laboratory and Mine Safety Appliances Co., Callery, Pa.

The pressure, temperature and plugging effects which result from a sodium-water reaction are based on the following equations:-

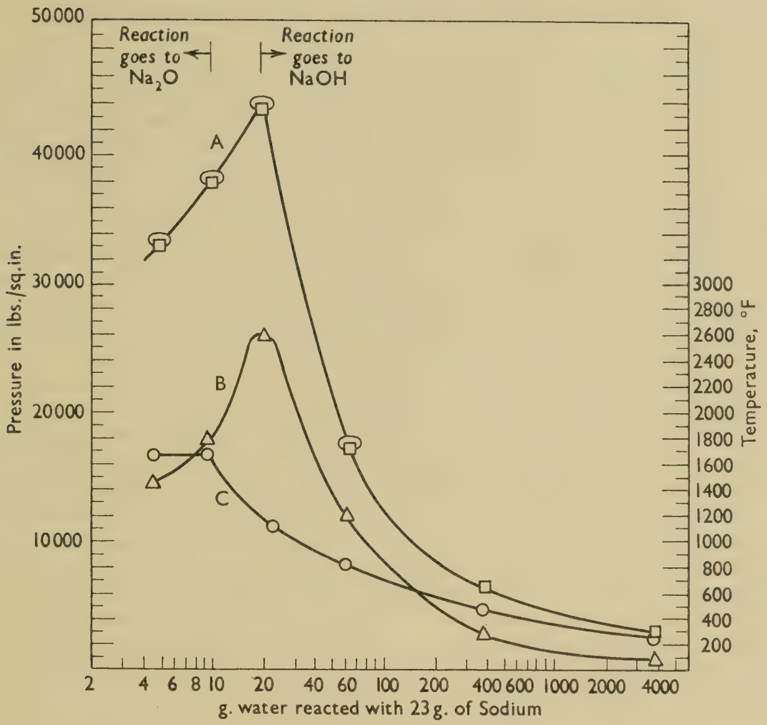

FIG. 1. ○ FINAL PRESSURE ISOTHERMAL REACTION
△ FINAL TEMPERATURE ADIABATIC REACTION
⊡ FINAL PRESSURE ADIABATIC REACTION
⊡ ASSUMING PERFECT GAS LAWS

(*a*) $Na(l) + H_2O(g) = NaOH(c) + 0{\cdot}5H_2(g) \quad H^\circ_{298} = -45{\cdot}7$ kg.-cal.
(*b*) $Na(l) + NaOH(c) = Na_2O + 0{\cdot}5H_2(g) \quad H^\circ_{291} = +1{\cdot}89$ kg.-cal.
(*c*) $Na(l) + 0{\cdot}5H_2(g) = NaH(c) \quad H^\circ_{298} = -13{\cdot}7$ kg.-cal.

Reaction (*a*) is extremely rapid, generally being limited only by the speed of mixing; the high sodium flow rates employed in heat-transfer systems facilitate rapid mixing and reaction. Reactions (*b*) and (*c*) are considered to be slow compared with (*a*). Should reactions (*a*) and (*b*) occur together the system pressure would be double that if reaction (*a*) occurred alone. The formation of sodium hydride would reduce the pressure build-up.

The thermal effects are largely influenced by reaction (*a*). Plugging effects arise from the fact that the solid reaction products are practically insoluble in sodium.

Three instances of leaks, which actually occurred in operating sodium-water heat exchanges, are described. In none of the leaks has there been evidence of a chemical reaction of sufficient violence to present a danger to operating personnel or adjacent equipment and in fact the sodium-water reaction of itself was not vigorous enough to indicate the leak; in each case it was detected indirectly by the plugging effects of the insoluble reaction products.

The shock effects resulting from the reaction of a water-to-sodium leak have been investigated.[33] The tests indicate that it is impossible to mix sodium and water fast enough through any conceivable leak in a heat-transfer system to obtain a reaction producing the shock waves characteristic of high explosives.

It has been shown by King[49,50] that the pressure resulting from the reaction when water is forced into sodium–potassium alloy, NaK, through a 0·25 inch pipe under a pressure differential of 200 pounds per square inch can be vented through a 1-inch relief valve set at 200 pounds per square inch. It has also been shown that the sharp pressure pulses resulting when the system is at room temperature are reduced as the temperature is increased. It is not expected that severe pressure pulses would result from leaks in heat-transfer systems operating at 600°F. or higher, since with sodium–potassium alloy initially heated to 600°F. the reaction with water proceeds to completion without pressure surges and the maximum pressure is essentially limited to the relief valve setting. Tests have also been carried out where sodium is in excess; in this case the pressure rise is reduced because of the rapid formation of sodium hydride.

It appears then that the reaction between sodium and water in practical heat-transfer systems will not generally result in mechanical damage to the system because of the absence of shock waves and the relative smoothness of the reaction at normal heat-exchanger temperatures. System plugging and subsequent problems in the removal of the reaction products may occur, however, if the leak is sufficiently large. System design recommendations to minimize the effects of leakage are given.[51] A large-scale experiment, devised to simulate the effect of a small steam leak into sodium in a sodium-superheated steam heat exchanger, gives results which show that the contents of the reaction vessel at room temperature are sodium, sodium hydroxide, sodium hydride with less than 0·1% peroxide. There is no visible corrosion of the stainless steel nozzle or equipment.[52]

Water vapour, emerging from a glass capillary tube at a pressure of 0·001–0·6mm.Hg on to a surface of sodium, does not attack the metal in the immediate proximity of the jet but at some distance away; the first signs of attack are denoted by a blue coloration and in time the reaction spreads throughout the length of the sodium plug. The above effects are much less regular when the capillary is made of metal in electrical connection with sodium.[53,54] The very slight action, *i.e.* the very small proportion of effective collisions which occur when a jet of water vapour impinges on an untarnished layer of sodium in a vacuum, is much enhanced if a high potential difference is established between the sodium and an electrode placed in the jet. The metal surface is rapidly covered with a film.[55] A revolving cylinder in an evacuated space cooled to −180°C. by liquid air and exposed on one side to a jet of sodium vapour and on the diametrically opposite side to a jet of water vapour, is coated with a thin layer of sodium which is bombarded with water vapour after half a revolution. The amount of hydrogen evolved is the same as that given with a similar jet of sulphuric acid, but with water vapour there is no luminescence. The reaction with water vapour may be trimolecular resulting in the direct formation of hydrogen molecules.[56]

The separation of hydrogen isotopes by displacement reactions of sodium with water, acids or bases has been described by several workers.[57-61] The metal is dissolved in the reagent of known deuterium content and the liberated hydrogen burned in a flame with a slight excess of oxygen. The proportion of the hydrogen isotopes in the water so formed is determined by density measurements. According to Johnston and Davis[61] the data are reproducible and confirm the applicability of the relationship, $d\ \ln(H) = \alpha d\ \ln(D)$, where (H) and (D) are instantaneous values of the amounts of protium and deuterium in the liquid phase, and α is the 'isotopic separation factor'. When the initial water contains 0·5% deuterium, the value of α at or near room temperature is 2·55–2·66. Hughes, Ingold and Wilson[59] give values of 2·8, 2·8, 3·0 and 2·9 for media ranging from strongly alkaline to strongly acidic. Horiuti and Szabo[58] obtain nearly the same value as Johnston and Davis[61] by using water vapour instead of liquid water. This implies that the reaction of sodium with liquid water occurs by a molecular and not an ionic mechanism.[61]

No reaction occurs, nor is any luminescence observed, when a freshly cut surface of sodium is exposed to the action of dry hydrogen at room temperature.[2] Pure sodium begins to absorb hydrogen appreciably at 100–110° C. and more rapidly as the temperature is raised. A mixture of sodium hydride and sodium is obtained.[62] Pure sodium hydride is obtained by leading a rapid stream of hydrogen directly on to the surface of sodium at a temperature above 350°; the sodium hydride is carried away as a white smoke which is precipitated electrically and filtered through glass wool.[63] The hydride is also prepared for use *in situ* by the action of hydrogen on high surface sodium dispersed on an inert solid, such as sodium chloride.[64] Sodium hydride may also be prepared for use *in situ*, as in the preparation of sodium borohydride (see page 498), by heating a mixture of molten sodium and a refined high boiling mineral oil agitated with a high shear in an atmosphere of hydrogen. The sodium dispersion technique increases the rate of formation of sodium hydride and the oily coating makes the sodium hydride easier to handle.[65]

Sodium has been used as a hydrogenation catalyst; it is unaffected by the usual catalyst poisons and is liquid at the temperature of the reaction. Vigorous agitation or admixture with an inert material is necessary to increase the surface of contact.[66]

From experimental values obtained over the temperature range of 289°C. to 415·5°C. the following equation has been derived for the dissociation pressure of sodium hydride: $\log p_{\text{mm.}} = -6100/T + 11{\cdot}66$.[67] Dissociation pressures have also been measured at 240–280° C.[68] and 310–380°C.[69]

Sodium hydride is quite stable when dissolved in sodium, as may be seen from Fig. 2, where a resulting stabilizing effect is observed on the normal dissociation pressure curve when, by the dissociation of sodium hydride in a mixture of metal and hydride heated in a closed system, sufficient sodium has been produced to dissolve all the remaining sodium hydride. The dissociation of sodium hydride is also depressed by the presence of an inert gas at pressures as low as 190mm.[70]

The dissociation pressure of the sodium/sodium hydride/hydrogen system has been measured at temperatures ranging from 500° to 600° C. and pressures as high as 4600 cm. and the results plotted as pressure versus composition and $\log p$ versus $1/T$. The first plot shows the isotherms as nearly horizontal lines which break away sharply at both ends of the composition axis (abscissae). The non-horizontal portions of the isotherms indicate the region of limited solubility of sodium and sodium hydride in the temperature range studied. The dissociation pressure of sodium hydride is essentially independent of the composition over the range 25 to 90% sodium hydride; the equilibrium pressures of both richer and poorer sodium–hydrogen composition phases however, are dependent on the composition, as may be seen from Table II.

The differential heats of dissociation have been calculated from the slopes of the $\log p$ versus $1/T$ plot and the following values estimated for the thermodynamic properties of sodium hydride:

$$\Delta H^\circ_{550} = 11{,}610 \text{ g.-cal./mole for } 100\%\text{NaH};\quad \Delta F^\circ_T = 11{,}610 - 17{\cdot}41T;$$
$$\Delta F^\circ_{25} = +6{,}410 \text{ g.-cal./mole for } 100\%\text{NaH};\quad \Delta S^\circ_{25} = 15{\cdot}5\text{e.u.};$$
$$\Delta H^\circ_{550} = 13{,}590 \text{ g.-cal./mole for } 30\text{–}80\%\text{NaH};$$
$$\Delta F^\circ_{25} = 7{,}730 \text{ g.-cal./mole for } 30\text{–}80\%\text{NaH};\quad \Delta S^\circ_{25} = 17{\cdot}7\text{e.u. for } 30\text{–}80\%\text{NaH}.$$

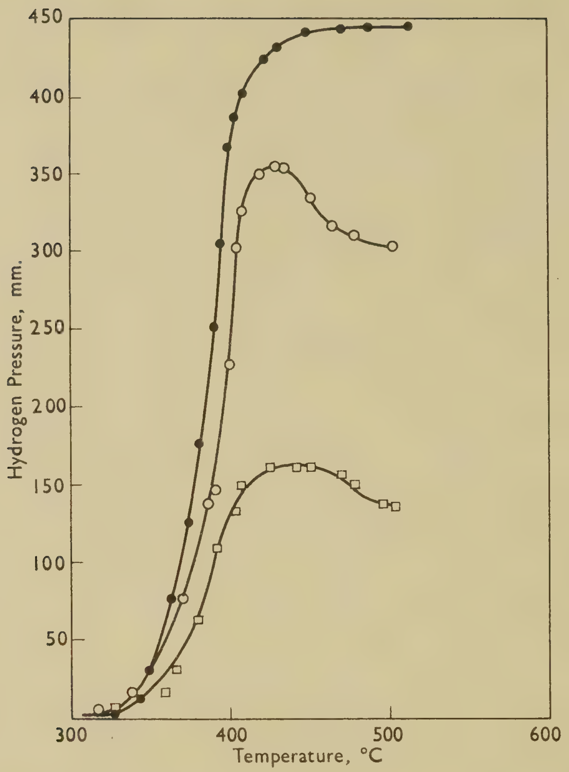

FIG. 2. THE SODIUM–SODIUM OXIDE–SODIUM HYDRIDE SYSTEM

TABLE II. - EMPIRICAL CONSTANTS FOR THE INTEGRATED CLAUSIUS–CLAPEYRON EQUATION: $\log P_{\text{cm.}} = -a/T + b$ FOR SODIUM HYDRIDE

%NaH	a	b
100	5070	9·49
90	5806	10·32
80–30	5958	10·47
20	6058	10·55
10	6222	10·70

It should be pointed out that unit activities of sodium and sodium hydride have been assumed in arriving at these data.[71] Herold gives −13·94 kg.-cal./mole for the heat of formation of sodium hydride calculated from dissociation pressure data.[67]

Other thermodynamic data given for sodium hydride are: $Na(c) + 0{\cdot}5H_2(g) \rightarrow NaH(c)$, $\Delta H(25°C.) = -13{\cdot}7$ kg.-cal./mole; for NaH(g), $\Delta H(25°C.) = -29{\cdot}88$ and $\Delta F(25°C.) = -24{\cdot}78$ kg.-cal./mole.[34] The heat of formation of sodium hydride calculated from the heat of hydrolysis of sodium and water corrected to infinite dilution and 25° C.: $Na(c) + H_2O(l) = NaOH(\infty) + 0{\cdot}5H_2(g) + 44{\cdot}23 \pm 0{\cdot}13$ kg.-cal./mole and from the heat of hydrolysis of sodium hydride and water corrected to infinite dilution and 25° C.: $NaH(c) + H_2O(l) = NaOH(\infty) + H_2(g) + 30{\cdot}63 \pm 0{\cdot}23$; has been found to be $-13{\cdot}60 \pm 0{\cdot}27$ kg.-cal./mole.[48] The heat of formation of sodium hydride at constant pressure at 25° C. is given as $-15{\cdot}69 \pm 0{\cdot}12$ kg.-cal./mole.[72]

Yasumori and Sato[73] have criticized Golden's reaction-rate theory when applied to the reaction $NaH + H \rightarrow Na + H_2$.

'Active' hydrogen reacts with sodium at −40° C., the 'active' hydrogen being produced by passing an electric discharge through hydrogen at a low pressure in the presence of sodium. With an initial hydrogen pressure of 743×10^{-3}mm.Hg, an accelerating potential of 94V. and a steady current of 546 microamp., the amount of hydrogen absorbed by sodium when the discharge is passed for ten minutes is such that the pressure is reduced to 336×10^{-3}mm. On heating the tube to 300° C. a volume of gas is liberated which is always less than the original volume absorbed and the absorption and evolution of hydrogen may be continued until finally a stage is reached when no further absorption occurs. The gas pressure is then 96×10^{-3}mm.Hg. When a lower accelerating potential is used, 54V., the final pressure is 202×10^{-3}mm.Hg. A modified apparatus which permits the absorption of larger amounts of hydrogen has been used to obtain sufficient reaction product for identification and it has been shown that with sodium-potassium alloy at −40° C. and an accelerating potential of 600V. the white crystalline material produced on the surface of the alloy is a mixture of sodium and potassium hydrides. A similar absorption of hydrogen by sodium occurs when the gas is ionized by α-rays from polonium.[74]

'Active' hydrogen is produced when (*a*) sodium is saturated with hydrogen at 200° C. and the temperature then raised until gas is liberated; (*b*) sodium is treated with hydrogen at 670° C.; (*c*) sodium is treated with hydrogen at 380° C. and the sodium hydride condensed and decomposed by water saturated with hydrogen.[75] Sodium vapour is excited to luminescence when exposed to Wood's 'active' hydrogen, *i.e.* atomic hydrogen produced by maintaining a powerful electric discharge through a long tube through which moist hydrogen is streamed at low pressures.[76] When an electric discharge excited by 5000V. is passed through a tube in which hydrogen at 0·05 to 0·1mm.Hg is streaming at a flow rate of about 1 litre/sec. and the gas then passed via a nozzle of 1 mm. diameter into a mixing chamber containing sodium vapour at about 0·1mm. pressure, a diffuse yellow glow becomes conspicuous at about 200°C. At higher temperatures the intensity of the light increases and is concentrated near the nozzle. Only the *D* line of sodium is present. It is considered that a three-body collision of two hydrogen atoms and a sodium atom takes place and part of the energy of recombination is expended in producing excitation of the metal atom.[77] Some chemiluminescence and quenching reactions of sodium in atomic hydrogen are described by Magee and Taikei.[78]

The linkage of atoms in a number of hydrides, including lithium and sodium hydrides, has been investigated by Tomiska, who has determined or computed the bonding forces, the distance separating the atoms and the character of the bonds. The force binding the atoms is a linear function of the number of external electrons in the molecule.[79]

References occur in the literature to the following compounds of sodium and mercury: Na_5Hg,[80] Na_3Hg,[80-85] Na_5Hg_2,[83-85] Na_3Hg_2,[81,83,84] $NaHg$,[81-84] Na_7Hg_8,[81,83,84] $NaHg_2$,[81-84,86] $NaHg_4$,[81-84,86] $NaHg_5$,[87] $NaHg_6$,[86,88] $NaHg_{16}$.[86]

The melting points of the amalgams, compiled by Biltz, Weibke and Eggers[84] are: Na_3Hg 35° C.; Na_5Hg_2 66° C.; Na_3Hg_2 119° C.; $NaHg$ 212° C.; Na_7Hg_8 222° C.; $NaHg_2$ 354° C.; $NaHg_4$ 156° C.

The heats of formation in g.-cal. per g.-atom of mercury of the following amalgams have been measured by means of a Bunsen ice calorimeter and are given in brackets: Na_3Hg(9·3); Na_3Hg_2(10·4); NaHg(11·3); Na_7Hg_8(10·6); $NaHg_2$(9·4); $NaHg_4$(5·6). The heat required to split off one g.-atom of liquid mercury from a mercury-rich compound to give the next lower one is: $NaHg_4$ −1·9; $NaHg_2$ −7·8; Na_7Hg_8 −5·3; NaHg −13·2; Na_3Hg_2 −11·4; Na_3Hg −9·3. These amalgams are definite chemical compounds immiscible or only slightly miscible with an excess of their components.[81]

The appearance of the following sodium–mercury compounds has been described: Na_3Hg, lustrous silvery flakes; NaHg, sparkling metallic needles with a pronounced reddish tinge; $NaHg_2$, silvery white crystals; $NaHg_4$, small lustrous silvery crystals.[82]

Liquid ammonia solutions of sodium react with mercuric iodide and cyanide and with mercurous iodide to form the compound NaHg which decomposes to sodium and the compound $NaHg_2$ (see page 515).

Sodium ignites in fluorine,[33] but when the gas is liquefied there is no reaction.[89] The metal may be distilled in dry chlorine without reaction.[90]

The following thermodynamic data are given for the reaction of sodium with the halogens: $Na(c) + 0{\cdot}5F_2(g) \rightarrow NaF(c), \Delta H^\circ_{298} = -136{\cdot}0$; $\Delta F^\circ_{298} = -129{\cdot}3$; $Na(c) + 0{\cdot}5Cl_2(g) \rightarrow NaCl(c), \Delta H^\circ_{298} = -98{\cdot}23$, $\Delta H^\circ_{500} = -98{\cdot}75$, $\Delta F^\circ_{298} = -91{\cdot}79$, $\Delta F^\circ_{400} = -90{\cdot}23$, $\Delta F^\circ_{500} = 87{\cdot}97$; $Na(c) + 0{\cdot}5Br_2(l) \rightarrow NaBr(c), \Delta H^\circ_{298} = -86{\cdot}03$; $Na(c) + 0{\cdot}5I_2(c) \rightarrow NaI(c), \Delta H^\circ_{298} = -68{\cdot}84$, ΔH and ΔF being expressed as kg.-cal./mole.[33,91]

Chlorine prepared by the action of sulphuric acid on a mixture of sodium chloride and manganese dioxide is found, after passage over potassium permanganate and a drying agent, to react with solid sodium almost as rapidly as moist air. A white reaction product is formed but no luminescence occurs. The reaction with bromine vapour is similar, whereas no reaction occurs with iodine, probably because its vapour pressure is too low at 20° C.[2]

Haber and Zisch have observed that when sodium vapour is allowed to react with chlorine diluted with nitrogen at atmospheric pressure so that the temperature is kept below that at which black-body radiation occurs, a reaction luminosity becomes faintly visible at 340° C. and the *D*-lines of sodium are easily seen at 473° C.[37]

The rate of reaction of sodium atoms with the halogens has been measured by the 'highly dilute flame' method, so called because the reaction is chemiluminescent. The method is particularly suitable for those reactions which occur at almost every collision. The reacting vapours are introduced at opposite ends of an evacuated tube at a pressure of about 10^{-3}mm.Hg and a temperature at which sodium vapour is largely dissociated into atoms. The reaction zone is several centimetres in length and the extent of the reaction is greater at the centre where most penetration occurs. The density of the distribution of the solid product deposited on the walls of the tube, and of the chemiluminescence produced, can be measured with accuracy and the velocity of the reaction estimated by analysis of the distribution of the reaction products. This method has been used to investigate the reaction of sodium vapour with chlorine, bromine and iodine.[92-97]

The luminescence produced in the sodium-halogen reaction has been examined in greater detail by introducing the halogen from a nozzle or jet into an excess of sodium vapour. The light distribution curve does not coincide with the precipitate-distribution curve and it is inferred that the reaction takes place in two stages: (*a*) $Na + Cl_2 \rightarrow NaCl + Cl + 40{\cdot}7$ kg.-cal., (*b*) $Cl + Na_2 \rightarrow NaCl + Na + 80$ kg.-cal., (*c*) $Na + Cl \rightarrow NaCl + 97{\cdot}5$ kg.-cal.; reaction (*c*) occurring on the walls of the reaction vessel. In the absence of a 'third' body, the reaction between sodium and chlorine atoms takes place only once in 10,000 collisions. The heats of reaction given in (*a*), (*b*) and (*c*) are not those given by the original workers, Bogdandy and Polanyi[96] but are recalculated from more recent data.[97] The luminescence accompanying the reaction is considered to result from the secondary reaction (*b*) because the intensity of the luminescence is diminished and almost completely extinguished by raising the temperature of the reaction zone, thus decreasing the number of sodium molecules present and increasing the number of sodium molecules dissociated into atoms. The chances for reaction (*b*) to proceed are therefore minimized by raising the temperature and it would appear that the luminescence is produced by the sodium chloride molecules formed in (*b*) carrying most of the energy of the reaction, colliding with other sodium atoms and exciting them to emission of the *D*-line; (*b*) $Cl + Na_2 \rightarrow NaCl^* + Na$; $NaCl^* + Na \rightarrow NaCl + Na^*$; $Na^* \rightarrow Na + h\nu$. This view has been confirmed, by quenching experiments with nitrogen.[92] All the gas reactions occur without activation energy.[96,97]

The reactions with bromine are: (*a*) $Na + Br_2 \rightarrow NaBr + Br + 40$ kg.-cal., (*b*) $Na_2 + Br \rightarrow NaBr + Na + 68$ kg.-cal., (*c*) $Na + Br \rightarrow NaBr + 86$ kg.-cal. As in the chlorine reaction the light yield is diminished by increasing the temperature of the reaction zone.[94]

Sodium vapour and iodine behave similarly: (*a*) $Na + I_2 \rightarrow NaI + I$; (*b*) $Na_2 + I \rightarrow NaI + Na + 54$ kg.-cal.; (*c*) $Na + I \rightarrow NaI + 68{\cdot}7$ kg.-cal. Again the light intensity is diminished by raising the temperature of the reaction zone.[93]

Sodium atoms react more readily with chlorine than with iodine atoms and this is in agreement with the thermodynamic values for the heats of dissociation of the sodium halides, calculated at absolute zero: NaCl 93·4 kg.-cal., NaBr 85·8 kg.-cal., NaI 68·7 kg.-cal.[93]

According to Nishibori the iodine molecule and sodium atom do not combine unless they approach in the region of dynamic collision in the sense of the dynamic theory of gases.[98]

The chlorine atoms, formed in the primary reaction when sodium atoms are present in a mixture of chlorine and hydrogen, induce a chain reaction by means of which several thousand molecules of hydrogen chloride are formed for each sodium atom reacting: $Na + Cl_2 \rightarrow NaCl + Cl$; $Cl + H_2 \rightarrow HCl + H$; $H + Cl_2 \rightarrow HCl + Cl$ and so on.[99,100]

In a similar manner the inducing effect of sodium atoms in a mixture of chlorine and methane is demonstrated: $Na + Cl_2 \rightarrow NaCl + Cl$; $Cl + CH_4 \rightarrow CH_3 + HCl$; $CH_3 + Cl_2 \rightarrow CH_3Cl + Cl$ and so on.[97]

The reactions of atomic sodium with halogens, halogen acids and alkyl halides are discussed from a kinetic point of view by Polanyi[101] and the mechanism of the reaction between sodium vapour and chlorine gas studied by means of molecular beams.[102]

A spectroscopic investigation of chemiluminescence observed when iodine is allowed to react in the vapour phase with sodium has been carried out by Lyalikov and Terenin[103] and the excitation of spectral lines by the action of sodium vapour with the halogens has been described.[103-106] Franck and Gibson[107] have studied the extinction of the *D*-lines in sodium flames by the addition of chlorine. The theory of the diffusion flame method for fast reactions with sodium atoms has recently been discussed by Reed and Rabinovitch.[108]

An energy diagram of sodium chloride has been constructed from curves representing the interaction energy of sodium and chlorine ions and atoms in the gaseous state and in solution.[109]

Molten iodine monochloride added dropwise to sodium wire reacts vigorously at first with the formation of sodium chloride; with small sticks of sodium there is a slight evolution of heat. The reaction is incomplete.[110] A slight heat of reaction is observed when molten iodine monobromide is added dropwise on to sodium in sticks; there is about 1% conversion to sodium bromide. Iodine monobromide is more reactive than iodine but less so than iodine monochloride.[111] A mixture of sodium and iodine monobromide explodes when subjected to shock by striking with a hammer.[112]

Hydrogen chloride prepared by dehydrating concentrated hydrochloric acid with sulphuric acid reacts very vigorously with sodium wire, converting it to sodium chloride; no luminescence accompanies the reaction.[2] An electron diffraction study of the white coating formed on the surface of sodium by the action of hydrogen chloride shows the presence of crystalline sodium chloride.[113]

Thermodynamic data for the reactions of sodium with the hydrogen halides are given below:-[33]

$$\mathrm{Na(c) + HF(g) \rightarrow NaF(c) + 0{\cdot}5H_2(g)},\ \Delta H^\circ_{298} = -71{\cdot}8,$$
$$\Delta F^\circ_{298} = -64{\cdot}6;\ \ \mathrm{Na(c) + HCl(g) \rightarrow NaCl(c) + 0{\cdot}5H_2(g)},$$
$$\Delta H^\circ_{298} = -76{\cdot}169,\ \Delta F^\circ_{298} = -69{\cdot}016;$$
$$\mathrm{Na(c) + HBr(g) \rightarrow NaBr(c) + 0{\cdot}5H_2(g)},\ \Delta H^\circ_{298} = -81{\cdot}370;$$
$$\mathrm{Na(c) + HF(g) \rightarrow NaF(c) + 0{\cdot}5H_2(g)},\ \Delta H^\circ_{298} = -75{\cdot}04.$$

In the above reactions, ΔH and ΔF are expressed as kg.-cal./mole.

Atomic reactions of sodium with hydrogen chloride carried out by the highly dilute flame method (described on page 450) are accompanied by chemiluminescence: $\mathrm{Na + HCl \rightarrow NaCl + H - 5}$ kg.-cal. The reaction velocities increase from hydrogen chloride to hydrogen iodide.[114] The above reactions require no activation energy.[115]

The rates of reaction of sodium atoms with hydrogen chloride and deuterium chloride have been measured by the diffusion flame method.[38,97] This method is particularly applicable to reactions which do not occur at almost every collision. Surface reactions are minimized by introducing the reactants in an inert gas so that the rate of diffusion is such that the sodium vapour leaving a nozzle is used up before it reaches the walls of the vessel. The distance to which the sodium penetrates is determined by a sodium resonance lamp. For the reaction: $\mathrm{Na + HCl \rightarrow NaCl + H}$, the rate is 0·412c.c. per mole per sec. and for $\mathrm{Na + DCl \rightarrow NaCl + D}$, it is 0·344c.c. per mole per sec. The activation energies calculated from the rates are 6·1 and 6·4 kg.-cal. respectively *i.e.* they differ by about 300 g.-cal. which is approximately equal to the difference between the zero-point energies in the initial and critical transition states of hydrogen chloride and deuterium chloride.[116]

Chlorine peroxide in aqueous solution is reduced by sodium amalgam to sodium chlorite: $\mathrm{Na + ClO_2 \rightarrow NaClO_2}$. The technical and economic aspects of the process, first patented by Finnois[117] have been reviewed by Nicolai.[30] The reactions which can take place are (*a*) $\mathrm{ClO_2} + e \rightarrow \mathrm{ClO_2^-}$; (*b*) $\mathrm{Na(Hg) \rightarrow Na^+ + Hg} + e$; (*c*) $\mathrm{ClO_2^- + 2H_2O} + 4e \rightarrow \mathrm{Cl^- + 4OH^-}$; (*d*) $\mathrm{2Hg \rightarrow Hg_2^{++}} + 2e$; (*e*) $\mathrm{2H^+} + 2e \rightarrow \mathrm{H_2}$; (*f*) $\mathrm{2ClO_2 + 2OH^- \rightarrow ClO_2^- + ClO_3^- + H_2O}$; (*g*) $\mathrm{8H^+ + 8ClO_2^- \rightarrow 6ClO_2^- + Cl_2 + 4H_2O}$. Optimum experimental conditions which favour reactions (*a*) and (*b*) and minimize reactions (*c*)–(*g*) result in a yield of more than 95% of a 20% sodium chlorite solution.

Sodium is attacked by the fumes of nitric acid at 15°C. and sodium nitrate is formed.[118] The action of nitric acid vapour has also been examined by mixing the acid with twice its volume of sulphuric acid and heating the mixture on a hot plate; previously dried air is passed over the surface of the acid into an observation chamber containing sodium at ordinary temperature. A slight glow is observed when the acid is heated at 40°C. and the light intensity increases as the temperature is raised to 85°C. The reaction is somewhat greater than with moist air.[2]

A very faint glow is observed when sodium is acted upon by previously dried air which has been passed over the surface of glacial acetic acid at

105° C. and through a calcium chloride tube into an observation chamber containing sodium wire.[2]

The heats evolved when solid sodium is acted upon by acetic and sulphuric acids are 53·7 and 68·5 kg.-cal./mole respectively, the values referring to the formation of the compounds in the liquid state.[119]

The reaction of sodium atoms with sulphuric acid vapour has been studied by allowing a jet of sodium vapour to impinge on one side of a cylindrical revolving drum in an evacuated enclosure and a jet of sulphuric acid vapour on the diametrically opposite side, the cylinder being cooled by liquid air to -180°C. Only the uppermost layer of sodium reacts with the acid forming a monomolecular protective layer of sodium hydrogen sulphate. The liberated hydrogen is evolved as atomic hydrogen, the reaction being accompanied by luminescence.[56]

Thomas and Rule[120] give the following solidification temperatures for the compounds and eutectic mixtures found in the sodium–sulphur system; Na_2S, >800° C.; Na_2S_2, 445·0°C.; Na_2S_2–Na_2S_3, eutectic, 206·0° C.; Na_2S_3, 223·5°C.; Na_2S_3–Na_2S_4, eutectic, 222·6° C.; Na_2S_4, 275·0°C.; Na_2S_4–Na_2S_5, eutectic, 247·6° C.; Na_2S_5, 251·8° C.; a saturated solution of sulphur in sodium pentasulphide solidifies at 249·6°C.

Pearson and Robinson[121] have confirmed the presence of the di-, tetra- and penta-sulphides in the sodium–sulphur system and give the following solidification temperatures: Na_2S, 978°C., stable at its melting point; Na_2S_2, 473·9°C., decomposes slightly at its melting point; Na_2S_4, 284·8°C., remarkably stable at its melting point. The upper arrest point for the pentasulphide is 254°C. The solid which separates out in the trisulphide area has a pearlite structure typical of a eutectic mixture; it is considered that sodium trisulphide decomposes at its melting point to give a mixture of di- and tetrasulphide. A phase diagram for the system[121a,b] is shown in Fig. 3.

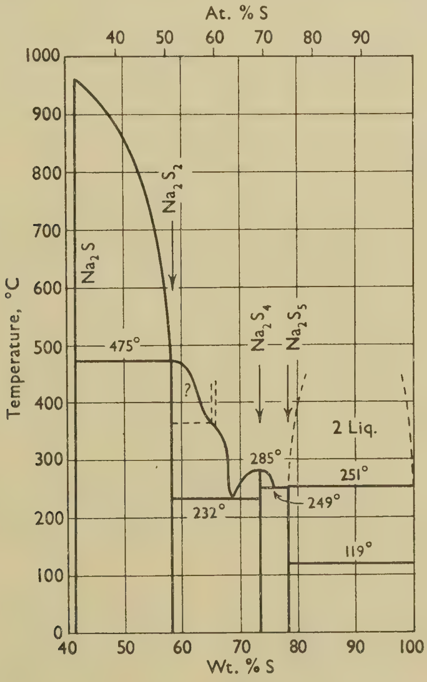

FIG. 3. EQUILIBRIUM DIAGRAM FOR Na-S SYSTEM

Neither Thomas and Rule nor Pearson and Robinson have found any indication of the tetrasodium compounds, Na_4S_3, Na_4S_5, Na_4S_7, Na_4S_9, described by Friederich and Mousset.[122] The compounds, Na_2S_3, Na_2S_6, and Na_2S_7, which cannot be obtained in the solid state from molten mixtures, have been shown to exist in liquid ammonia solution[123] (see also page 510).

Fehér and Berthold,[124] by modifying the procedure described in [121,125], have prepared sodium tetrasulphide by heating a solution of sodium in ethanol, saturated with hydrogen sulphide, with sulphur, and removing the alcohol under reduced pressure.

Anhydrous sodium disulphide is formed when an alcoholic solution of sodium tetrasulphide, (prepared from 4·95g. of sodium in 150ml. of alcohol and 10·35g. of sulphur) is reduced with small pieces of sodium, total weight 9·5g.[124]

The preparation of polysulphides by the action of sodium on molten sulphur is unsatisfactory because the reaction is so violent. Locke and Austell[126] found that the reaction could be modified by allowing the elements to react under boiling toluene but that under these conditions only the trisulphide with some tetrasulphide could be obtained. Draves and Tartar[127] treated excess sulphur in boiling toluene with sodium, using an atmosphere of hydrogen to exclude air and moisture, and found that in the product, which had been dried overnight at 20mm. pressure in an atmosphere of hydrogen, the atomic ratio of sulphur to sodium was 2·989:2, 3·007:2, 3·091:2 and 3·172:2 in four tests. Pearson and Robinson[121] have observed that when clean sodium is melted in dried toluene, heated under reflux, and sulphur added in 0·5g. portions, the sodium is immediately coated with a yellow coherent film, and when 1·5 atomic proportions of sulphur have been added the film bursts and the escaping sodium reacts vigorously with the dissolved sulphur. It is necessary to cool the flask with water; otherwise a small amount of carbon is produced. After boiling for a further 20 minutes to complete the reaction, the product is quickly filtered, washed with cold toluene and dried at 100°C. for 2 hours under a good vacuum. It would appear that the first product formed in the above reaction is a polysulphide, because even when only a trace of sulphur is used there is no indication of a white film, which would be present if sodium monosulphide were formed; instead, the metal surface is partially coated with distinctly yellow patches. However much sulphur is used, no compound other than the trisulphide is formed.

More recently Fehér and Berthold[124] have repeated the above work and shown that when the amount of sulphur used is that required for the formation of the trisulphide, the product contains a small amount of free sodium, *i.e.* a polysulphide higher than the trisulphide is formed. When the requisite amount of sulphur for the pentasulphide is used, the product has the composition of $Na_2S_{3.5}$ or $Na_2S_{3.3}$.

The hydrates, $Na_2S_2,6H_2O$, $Na_2S_3,8H_2O$, $Na_2S_4,8H_2O$, $Na_2S_4,9H_2O$, Na_2S_4,-$11H_2O$ and $Na_2S_5,6H_2O$ have been prepared by Pearson and Robinson[121] by converting sodium to sodium monosulphide in aqueous alcoholic solution, treating the solution with the theoretical amount of sulphur and cooling in freezing mixtures.

Sodium sulphide is produced by dissolving sulphur in an aqueous solution of sodium sulphide, *i.e.* in some of the product, and reducing the polysulphide with sodium amalgam to sulphide. The economic aspect of this process is discussed by Nicolai.[30]

A method of investigating chemical reactions in the solid phase is described by Semenov and Shalnikov,[128] the reactants being sodium and sulphur. The two substances are evaporated simultaneously on to a surface cooled with liquid air and enclosed in a high vacuum so that an extremely intimate mixture is formed. When the evaporated layer becomes so thick that its surface is above a certain critical temperature, a very rapid reaction occurs in an elliptical zone having its centre approximately at the point of thickest deposit, and proceeds inwards towards the surface cooled with liquid air spreading sideways from the thickest point, the heat of reaction warming the interior to the critical temperature.

A low pressure reaction between sodium atoms and sulphur occurs at and above 300° C. and is accompanied by chemiluminescence, the *D*-lines of sodium being displayed with a continuous background.[129]

Sodium dispersions are used to remove sulphur compounds, including thiophen, from petroleum.[130]

The solubility of selenium in sodium is given by the expression, $w = -8{\cdot}4 + 0{\cdot}0858t$ where w = wt.-% and t = °C.[33]

Sodium reacts with selenium in liquid ammonia to form the compounds: Na_2Se, Na_2Se_2, Na_2Se_3, Na_2Se_4, Na_2Se_5 and Na_2Se_6,[123] (see also page 511).

The phase diagram prepared by thermal analyses by Mathewson in 1907 does not include the compound Na_2Se_5.[131]

Chemiluminescence is observed in the low pressure reaction between sodium atoms and selenium at and above 300°C.[129]

Sodium reacts slowly in the cold with selenium monochloride forming sodium chloride and selenium; the reaction soon stops, however, owing to the presence of insoluble sodium chloride. On heating, the reaction proceeds vigorously with the evolution of light and heat.[132]

Potentiometric titrations of tellurium with a liquid ammonia solution of sodium give points of inflexion at compositions corresponding to: Na_2Te, Na_2Te_2, Na_2Te_3, Na_2Te_4.[123] For details of reactions in liquid ammonia, see also page 511.

Kraus and Glass[133] have measured the electrical resistance of liquid mixtures of sodium telluride, Na_2Te, and tellurium at concentrations up to 54at.-% of sodium and temperatures up to 500° C. It is inferred that sodium and tellurium form a compound Na_2Te_6 which has a congruent melting point at 436° C. A phase diagram for the system[121a,b] is shown in Fig. 4.

Sodium and tellurium are completely miscible in the liquid phase, and in addition to the normal telluride, Na_2Te, two other compounds, Na_2Te_2 and Na_2Te_6, are formed as well as two eutectics, Na_2Te–Na_2Te_6 and Na_2Te_6–Te. The transition point for Na_2Te_2 and Na_2Te lies at 355° C.[134]

The solubility of tellurium in sodium up to 700°C. is given by the equation: $w = -8{\cdot}1 + 0{\cdot}083t$ where w = wt.-% and t = °C.[33]

Kraus and Ridderhof[135] give the heats of formation of the compounds, Na_2Te and NaTe, as 28·1 and 25·4 kg.-cal./g.-atom respectively from measurements made of the heats of reaction and heats of solution in liquid ammonia at −34°C.

Although a vigorous reaction occurs when liquid tellurium is poured over solid sodium, Kubaschewski[136] has been able to measure the heat evolved by carrying out the reaction in an atmosphere of argon: the results given in Table III enable the heats of formation of the compounds Na_2Te, NaTe and

NaTe$_3$ to be calculated as: 20 ± 2; 15 ± 1·5 and 7·5 ± 0·8 kg.-cal./g.-atom, respectively.

A very faint characteristic greenish-blue light is emitted when dry hydrogen sulphide is passed over sodium wire. With moist hydrogen sulphide a very rapid reaction occurs, sufficient heat being produced to melt the sodium.[2]

For the reaction: $2Na(c) + H_2S(g) \rightarrow Na_2S(c) + H_2(g)$, $\Delta H^\circ_{298} = -84{\cdot}385$ kg.-cal./mole.[33]

The rate of reaction of sodium atoms with hydrogen sulphide has been studied by the diffusion flame method as already described for oxygen (see page 442) with the results given in Table IV.

The mechanism of the reaction is given by the following equations: (*a*) $Na + H_2S \rightarrow NaH_2S^*$; (*b*) $NaH_2S^* \rightarrow Na + H_2S$; $NaH_2S^* + N_2 \rightarrow NaH_2S + N_2^*$. At low inert gas pressures, the rate of the reaction is determined by a three-body collision, the nitrogen carrying away the energy of the reaction. At high nitrogen pressures reaction (*b*) does not occur to any appreciable extent and the reaction becomes bimolecular.[41]

Sodium reacts quite readily with dry ammonia at room temperature to form sodamide and hydrogen; the reaction is not accompanied by luminescence.[2] At 300° C., molten sodium reacts rapidly, and the reaction may be utilized to

TABLE IV. - REACTION OF SODIUM VAPOUR WITH HYDROGEN SULPHIDE AT 238°C.

clean up equipment containing sodium residues. The amide decomposes at higher temperatures to give sodium, sodium hydride, nitrogen and hydrogen.[33]

Sodium vapour has a negative catalytic effect on the decomposition of ammonia in a glow discharge.[137]

Sodium dissolves in liquid ammonia to give intense blue solutions and in the absence of catalysts and at ordinary temperatures a slow reaction occurs resulting in the formation of sodamide and hydrogen. The heavier the alkali metal the more readily it reacts with liquid ammonia; under comparable conditions the times of reaction are: lithium and sodium several days, potassium 60 minutes, rubidium 30 minutes, caesium 15 minutes.[138]

Liquid ammonia solutions of sodium exposed to short ultra-violet light (2144–2550A.) give off hydrogen and the sodium is converted into sodamide. The intense blue colour of liquid ammonia solutions of sodium fades rapidly on exposure to the intense radiation from a quartz-mercury lamp, and a pale yellow solution of the amide is produced. Illumination for a few minutes with the full radiation from a cadmium spark results in the development of considerable gas pressure.[139]

Burgess and Kahler have studied the catalytic effect of silver, zinc, nickel, thallium, iron and platinum on the reaction between sodium and liquid ammonia at its boiling point, and found that platinized platinum, nickel, rusted iron and ferrous oxide are the most efficient catalysts. As adsorbed air films reduce the effectiveness of the catalyst, the apparatus should be evacuated before introducing ammonia. Increase of rate of stirring increases the rate of reaction but no further effect is observed at a rate above 250 r.p.m. The accumulation of sodamide in solution appears to poison the catalyst.[140] Watt, Barnett and Vaska[141] have also studied the catalyzed reaction between sodium and liquid ammonia. The reaction is catalyzed by metals in general and most effectively by those of the transitional series. It is unfortunate that some of the most effective catalysts are the metals most commonly used as materials of construction. Rate measurements have been made by collecting the hydrogen evolved during the catalyzed reaction and the following results are expressed as (c.c.H_2/h./g.Na/sq.mm. catalyst area) × 10^2: tantalum, 0·24; monel, 1·0; stainless steel (Carpenter 20), 5·1.

The following value has been given for the heat of formation of sodamide:

$Na(c) + 0{\cdot}5N_2(g) + H_2(g) = NaNH_2(c) + 27$ kg.-cal.[138,142]

Dry sulphur dioxide does not react with sodium at room temperature but the moist gas reacts almost as vigorously as water though without luminescence.[2] Only a partial dulling of the surface of sodium is observed after storage in liquid sulphur dioxide for several months.[143] Liquid sodium reacts with sulphur dioxide to give sodium sulphide and sulphate: $4Na + 2SO_2 \rightarrow Na_2S + Na_2SO_4 + 18{\cdot}24$ kg.-cal.[33]

It is believed that alkali metal hyposulphites have not been prepared successfully by the direct action of sulphur dioxide on sodium. When, however, the alkali metal is in the form of an addition product with certain ethers, the hyposulphite can be obtained in good yield by the action of sulphur dioxide. An example is given: 100 parts of a dispersion of sodium in xylene (50%Na) are added to a reaction vessel containing ethylene glycol dimethyl ether. The mixture is stirred and sulphur dioxide continuously passed at a temperature of 10°C. When the reaction subsides the stirring and passage of sulphur dioxide are stopped and the sodium hyposulphite, which is in the form of a white precipitate, is separated by means of a centrifuge, washed with alcohol and ether and dried. Other ethers of polyhydric alcohols which may be used are listed. Sodium hyposulphite is also formed when sulphur dioxide is allowed to react with sodium-naphthalene or sodium-benzophenone addition compounds in ethylene glycol diethyl ether but is contaminated with naphthalene and benzophenone.[144]

The manufacture of sodium dithionite (hydrosulphite, hyposulphite, $Na_2S_2O_4$) from sulphur dioxide and sodium amalgam is described by Dijs, Hoogland and Watermann.[145] Sodium amalgam is passed by a centrifugal pump at the rate of 1 l./min. from an electrolyzer to the top of a reactor where it divides into droplets and comes in contact with a buffer solution made up of a 5% solution of sodium bisulphite–sodium sulphite of pH 5–5·5. As soon as the circulation of the solution and amalgam is started, sulphur dioxide is passed into the reactor at a rate which maintains the desired pH value. With a buffer solution of pH less than 5 low yields are obtained; at pH values greater than 5·5 hydrogen sulphide is obtained as one of the reaction products. The temperature must be less than 40°C. By feeding buffer solution into the reactor and drawing off an equal volume of sodium dithionite solution, the process becomes entirely continuous. The denuded amalgam falls to the bottom of the reactor and is returned by gravity flow to the electrolyzer. The process can be automatically controlled. Sodium sulphide is used to precipitate small amounts of dissolved mercury in the form of the sulphide, HgS, which may be removed by filtration. A 15% solution of the dithionite can be obtained with a yield of 80–90% calculated on the current consumption, and a yield of 90% based on sodium amalgam used. The procedure and apparatus used for the continuous production of an aqueous solution of sodium dithionite from sodium amalgam and sulphur dioxide have also been described.[146] The reactions occurring are: $2Na_2SO_3 + 2H_2O + 2SO_2 \rightarrow 4NaHSO_3$ and $4NaHSO_3 + 2Na \rightarrow Na_2S_2O_4 + 2Na_2SO_3 + 2H_2O$. The temperature should be 10°–25°C., preferably above 15°C., and the pH of the solution 5·4–5·8. The dithionite solution should remain in the reactor as short a time as possible to prevent the formation of thiosulphate, and the solution should be as concentrated as possible in order to effect separation by addition of sodium chloride. In this process two reactors are used, the buffer solution reacting separately with sulphur dioxide and the amalgam respectively. An equally intensive circulation is necessary between the two reactors. After treatment with sulphur dioxide the solution is cooled before treatment with sodium amalgam. The concentration of the amalgam is preferably 0·01–0·05% and it is important that the amalgam should be discharged before it is completely denuded, *i.e.* when the concentration has fallen to 0·001–0·002%. With a buffer solution of sulphite–bisulphite with concentrations of sulphur dioxide up to 70g./l. and with an introduction of gaseous sulphur dioxide in stoicheiometric ratio with the sodium as amalgam it is possible to obtain solutions of dithionite to the solubility limit capable of giving a solid product with a titre over 85%$Na_2S_2O_4$ and yields between 50% and 65%. From buffer solutions containing at least 15g./l. of sulphur dioxide, yields of 70–80% of dithionite solutions containing 40g./l. $Na_2S_2O_4$ can be obtained. There are numerous other references to the reaction of sulphur dioxide with sodium amalgam.[28,30,147-153]

Aqueous sodium thiosulphate solutions are reduced with sodium amalgam to yield equimolecular proportions of sulphide and sulphite ions. It is assumed that reduction is brought about by sodium atoms rather than by an electrical charge removal since the S_2O_3 ion is not reduced at the dropping-mercury electrode for voltages up to −2·5V. (against saturated calomel) whereas the potential with sodium amalgam is about −2·15V.[154]

The reaction of sodium vapour with sulphur dioxide and trioxide at 238° C. and at low pressures has been studied by Bawn and Evans by the diffusion flame method already described (see page 442). Both of these gases show remarkable reactivity towards sodium atoms, reaction occurring at about one collision in ten. The mechanism of the reaction is given by the following equations where X represents sulphur dioxide or trioxide: $Na + X \rightarrow NaX^*$; $NaX^* \rightarrow Na + X$; $NaX^* + N_2 \rightarrow NaX + N_2$. Nitrogen acts as a third body, carrying away the energy of the reaction. The results are given in Table V.[41]

The rate of reaction of sodium atoms with sulphur hexafluoride has been measured by the diffusion flame method. A thick film of sodium is deposited *in vacuo* on the side of a Pyrex tube and sulphur hexafluoride introduced at a pressure up to 10mm.Hg. At room temperature no reaction occurs but at 200–300° C. the pressure falls to less than 0·1mm. in eight minutes and the sodium surface is covered with a brown incrustation. With sulphur hexafluoride at 235·5mm. and at 300° C. the reaction stops after only 10mm. of gas is absorbed. At 500° C. the reaction is accompanied by luminescence of the sodium *D*-line. The gas-phase reaction: $SF_6 + Na \rightarrow SF_5 + Na^+F^-$, is exothermic, about 37 kg.-cal. being evolved; with a sodium surface the reaction would be even more exothermic. The chemiluminescence is probably caused by one of the five stages of the reaction: $SF_n + Na \rightarrow SF_{n-1} + Na^+F^-$ ($n \leq 5$) which is exothermic to a greater extent than 49 kg.-cal., the energy required to excite the *D*-line. The bimolecular velocity constant at 247° C. is $2{\cdot}23 \times 10^{13}$c.c. per mole per sec.[155]

Sodium begins to react with the vapour of thionyl chloride at 100° C., the surface of the sodium becoming covered with a protective film of sodium chloride which prevents further action. At 300° C. a considerable amount of sulphur monoxide is formed and the reaction proceeds with the production of a flame: $SOCl_2 + 2Na \rightarrow 2NaCl + SO$.[156]

According to Hubbard and Luder the reaction with boiling thionyl chloride is very slow.[157]

Diethyl sulphite, $SO(OC_2H_5)_2$, does not react with sodium at 300° C. and the metal may be distilled unchanged.[156]

The atomic reactions of sodium and sulphur mono- and di-chloride at 270° C. have been studied by the diffusion flame method, the partial pressure of the sodium being about 3×10^{-3}mm.Hg and that of the inert carrier gas, nitrogen, 1–10 mm.Hg. The reaction with the dichloride is almost instantaneous, reaction occurring at practically every collision. The velocity constant is 6340c.c.mole^{-1}sec.$^{-1}$ $\times 10^{-11}$. The reaction with the monochloride is slower, the collision number being about 3·6 and the velocity constant 1760 c.c.mole^{-1}sec.$^{-1}$ $\times 10^{-11}$. Both reactions are accompanied by a blue luminescence but the light intensity is greater with the dichloride.[158]

A mixture of sodium and sulphur dichloride explodes when hit with a hammer.[112]

When solid sulphides of the non-noble metals, with the exception of magnesium, are intimately mixed with alkali metal amalgams in the presence of sufficient water for reaction (with the exclusion of air or in a protective atmosphere and at an elevated temperature) the non-noble metals are precipitated quantitatively and in powdered form. Alkali metal sulphides are formed. The reaction may be conducted in the molten state or in the gaseous phase, preferably in a closed cycle and continuously.[159]

Nitrogen does not appear to react with sodium and is in fact recommended for blanketing liquid sodium during handling.[9] A method, probably originating with Bunsen in the Heidelberg laboratory, for obtaining lustrous sodium by filtering in nitrogen is described by Bornemann.[160] A clean, dry glass tube about 15–20 mm. wide is sealed at one end and a constriction of diameter 3–4 mm. is made at about 20cm. from the bottom. A clean metal sieve (1mm. mesh) is placed at the constriction so as to press tightly against the sides of the tube, and freshly cut sodium is placed on the sieve and the tube sealed off at about 20cm. above the constriction. The metal forms oxide which absorbs carbon dioxide in the air leaving only nitrogen in the tube. After some hours the metal is carefully melted, with the tube in a horizontal position to prevent the molten metal passing the sieve, and if on cooling and standing for some time the metal remains lustrous, the tube is placed in a vertical position and heated at first from the sieve down to the constriction and later up to the metal. The metal flows through the sieve but the carbonate, hydroxide or oxide does not. The tube is finally sealed off at the constriction.

Guernsey and Sherman[161] have shown that when nitrogen heated to 1000° C. is passed over sodium at 800° C., neither sodium nitride nor azide is formed. Iron has no catalytic effect.

The reaction between strontium and nitrogen to form strontium nitride is accelerated by sodium.[162] Sodium acts as an 'exciter' in the calcium/nitrogen reaction and after the reaction is started it proceeds more rapidly if the sodium is removed from the surface of the calcium.[163] Nitrogen is removed from argon by treatment with calcium activated with sodium. Calcium activated in this way reacts a hundred times faster with nitrogen than does untreated calcium. Spectroscopically pure argon is easily prepared in this way.[164]

Fischer and Schröter[165] state that sodium nitride, contaminated with a fine metallic dust mostly black in colour, is formed when an electric discharge is passed between sodium electrodes through a liquid mixture of 90% argon and 10% nitrogen. This contaminated sodium nitride is considered by Moldenhauer and Mottig[166] to be a mixture of sodium azide and sodium.

Wattenberg[167] has subjected nitrogen, at a pressure of 1–10mm. Hg, to the action of an electric discharge in the presence of finely divided sodium and obtained the results given in Table VI.

TABLE VI. - REACTION BETWEEN SODIUM AND ACTIVATED NITROGEN

Time min.	c.c. N_2 at 0° C. and 760mm.	Reaction product	
		% Nitride	% Azide
1	0·5	100	-
5	0·9	100	-
110	1·6	54	46
264	4·1	27	63

Sodium nitride and activated nitrogen have been shown to give sodium azide.

The literature on the stability, thermodynamics and photochemistry of the metallic salts of hydrazoic acid has been reviewed by Racz;[168] the equilibrium constants calculated for the possible formation of the sodium derivatives are shown in Table VII.

TABLE VII. - EQUILIBRIUM CONSTANTS FOR THE REACTIONS:

According to Kichlu, sodium is ionized when acted upon by active nitrogen.[169] The transfer of energy between active nitrogen and sodium has also been described: active nitrogen, liberated by thermal decomposition of silver azide, excites ultra-violet fluorescence in certain metallic vapours and, under vacuum at 272° C. and in the presence of sodium (0·01mm.), the emission is four times as intense as with silver azide alone.[170]

In the presence of carbon and metal oxides, sodium reacts with nitrogen to form sodium cyanide.[33]

Sodium and phosphorus, when heated together in the atomic ratio of 3:1 in an argon atmosphere in a corundum crucible enclosed in a gas-tight iron container, yield a homogeneous product, Na_3P, which is extremely sensitive to air. This compound does not appear to be formed when the elements are brought together in liquid ammonia.[171]

The conditions for the preparation of the compound, Na_2P_5, described by Hackspill and Bossuet[172] have been found by studying the thermal dissociation of sodium dihydrogen phosphide, NaH_2P. Below 100° C., this compound dissociates giving a yellow amorphous powder of disodium hydrogen phosphide and liberating pure hydrogen phosphide: $2NaH_2P \rightarrow Na_2HP + PH_3$; the dissociation pressure of disodium hydrogen phosphide is inappreciable up to 100° C., but the proportion of phosphine in the gas evolved between 100° and 150° C. decreases and the amount of hydrogen increases owing to the reaction: $Na_2HP \rightarrow 2Na + P + 0{\cdot}5H_2$. At 380°C. the vapour pressure of sodium is sufficiently high for some distillation to occur, and by very careful distillation over a period of 150 hours at 450°C. a yellow product, Na_2P_5, is obtained: $5Na_2HP \rightarrow Na_2P_5 + 8Na + 2{\cdot}5H_2$.[173]

Sodium reacts with phosphorus in the presence of air to form sodium phosphate.[33]

A brown-violet powder of composition Na_3As is obtained when sodium vapour is passed over heated arsenic in a hard glass tube which has been previously evacuated.[171] No indication of compound formation is given by potentiometric titrations of elementary arsenic in liquid ammonia solutions of sodium, but when liquid ammonia solutions of arsenic trisulphide are used the following compounds are shown to exist: Na_3As, Na_3As_3, Na_3As_5 and Na_3As_7[123] (see also page 511).

Arsenic and arsine are formed when arsenic trioxide in an aqueous buffered solution is reduced with sodium amalgam (0·6%Na). At pH 8·5 the fraction of reduced arsenic appearing as the metal varies from 13·2 to 1·3% as the initial concentration of As(III) varies from 0·1 to 0·01mole/l. The formation of arsenic is favoured by increase of temperature. The fraction reduced to arsenic with a solution of 0·051mole/l. As(III) increases from 11·5 to 68·2% as the pH is increased from 8·5 to 14·3. In the presence of excess of sodium amalgam arsenic is first formed and then reduced to arsine with hydrogen formed by reaction of sodium with water.[174]

Sodium thioarsenate solutions are reduced by sodium amalgam to yellow arsenic which forms as a precipitate and is soluble in and may be crystallized from carbon disulphide. This form of arsenic is converted by light into ordinary arsenic.[175]

A bluish-gray compound with a metallic lustre, Na_3Sb, is formed when sodium and antimony are heated together in an atmosphere of argon in the atomic ratio of 3:1 at a temperature about 50° to 100° above the melting point. The reaction may be carried out in a stoppered iron crucible.[171] For reactions in liquid ammonia, see page 512.

Sodium hydroxide solutions of antimony oxide, Sb_2O_3, buffered at pH 8·53, are reduced by 0·5% sodium amalgam and yield less stibine, SbH_3, more antimony and more trivalent ion, Sb^{+++}, in solution in thirty minutes than the corresponding products from arsenic trioxide solutions. The absolute yield of stibine is practically constant for Sb(III) concentrations above 2%; the antimony yield is greater than the sum of stibine and dissolved ion, Sb^{+++}, and both the antimony and ion yields increase with Sb(III) concentration. The stibine fraction increases with decreasing Sb(III) concentration but is less when nitrogen is used as carrier gas than when carbon dioxide is used; it is also less at 60° than at 20°C. and after 30 minutes rather than 60 minutes.[176]

A mixture of sodium and phosphorus pentachloride or tribromide explodes violently when struck with a hammer.[112]

The reactions between phosphorus trichloride, phosphorus oxychloride, arsenic trichloride and sodium vapour at 270°C. and about 3×10^{-3}mm., in the presence of an inert carrier gas such as nitrogen at 1–10mm. pressure, have been studied by Heller and Polanyi.[158] Phosphorus oxychloride reacts more readily than phosphorus trichloride, which reacts at about the same rate as arsenic trichloride. The reaction velocity constants expressed as c.c.mole^{-1} sec.$^{-1}$ × 10^{11} are: 2290($POCl_3$), 1500(PCl_3), 1470($AsCl_3$). The first two reactions are accompanied by luminescence, the oxychloride reaction emitting a bluish-grey light, and the phosphorus trichloride reaction emitting the *D*-line of sodium. No luminescence is observed with arsenic trichloride.

Nitrous oxide reacts with sodium to form sodium oxide and nitrogen: $2Na + N_2O \rightarrow Na_2O + N_2$; $\Delta H^\circ_{298} = -118{\cdot}89$; $\Delta F^\circ_{298} = -114{\cdot}76$ kg.-cal./mole.[33]

The diffusion flame technique has been used by Bawn and Evans[41,177,178] to study the rates of reaction of sodium vapour at low pressures with oxides of nitrogen at about 260° C. The reactions with nitrous oxide and nitrogen peroxide are accompanied by a marked luminescence, that with the former being the much more intense; with nitrous oxide, reaction occurs at about one collision in forty and with nitrogen peroxide at about one in ten. Experimental details and results for these two oxides are given in Table VIII.

The following mechanism is postulated: $Na + N_2O \rightarrow NaO + N_2$; $NaO + Na_2 \rightarrow Na_2O^* + Na$; $Na_2O^* + Na \rightarrow Na_2O + Na^*$; $Na^* \rightarrow Na + h\nu$.[178]

The reaction of sodium vapour with nitric oxide has been studied by the foregoing method and also by a modified streaming method permitting higher inert gas pressures to be used. The results for the streaming method, given in Table IX, are considered to be the more accurate.

The reaction occurs according to the following mechanism: $Na + NO \rightarrow NaNO^*$; $NaNO^* \rightarrow Na + NO$; $NaNO^* + N_2 \rightarrow NaNO + N_2$. A termolecular reaction occurs at low inert gas pressures; the unstable associated molecule, $NaNO^*$, which has a lifetime of about 10^{-9} seconds, dissociates or is stabilized by subsequent collision with a nitrogen molecule. At higher inert gas pressures, the reaction changes over to a simple bimolecular mechanism.[41]

When shaken with sodium amalgam, nitric oxide reacts to form the compound, NaNO, which is found by *X*-ray diffraction to be identical with the compound formed when nitric oxide reacts with sodium in liquid ammonia but different from sodium hyponitrite. The compound is obtained in quantitative yield.[179]

When sodium is heated in nitrogen containing about 20% of nitric oxide, the metal becomes bluish-green at about 60° to 70° C. and reaction sets in at about 160° to 170° C. The solid yellow product dissolves in ice-cold water to give an alkaline solution of sodium nitrite and hyponitrite, $Na_2N_2O_2$, and nitrous oxide is evolved.[180]

A mixture of sodium nitrite and nitrate is produced when sodium is burnt in gaseous dinitrogen tetroxide.[13] At the temperature of burning sodium, the gaseous phase contains oxygen and nitric oxide which give rise to the nitrite. Crystallographic analysis of the reaction products formed when liquid dinitrogen tetroxide is treated with sodium show the white solid product to be crystals of sodium nitrate. A marked increase in the speed of the reaction occurs when a potential difference is applied while the reaction is taking place.[181] The reaction of metallic sodium with a gaseous mixture of N_2O_4–NO_2 molecules has been studied by passing the gas mixture over the metal at 60° to 80° C. and at atmospheric pressure. A thin coating of a white solid is acquired in about 15 minutes and then becomes sufficiently cohesive to prevent further action. An *X*-ray powder photograph of the product is identical with that of pure sodium nitrite.[182]

Nitrogen peroxide is liberated and a white crystalline solid identified as sodium nitrate is formed when small pieces of sodium are added to liquid nitrogen pentoxide at −40° C.[181]

Sodium reacts with sodium nitrite in liquid ammonia to form a bright yellow precipitate of disodium nitrite, Na_2NO_2. This compound is also formed when a solution of sodium nitrite in liquid ammonia is electrolyzed, and is seen as a bright yellow deposit on the cathode[183,184] (see also page 518).

The rates of reaction of sodium atoms with nitromethane, ethyl nitrate and amyl nitrite have been measured by the diffusion flame method, with the results given in Table X.[178]

Neither graphite nor diamond appears to react with sodium at any temperature, and dry graphite powder can in fact be used to smother sodium fires.[33,143,185,186] Herold[187] states that sodium does not react with graphite even at 500° C. Blue or black products, poor in alkali metal, obtained by operating at 900° C. in mild steel, suggested that sodium does in fact form compounds with carbon analogous to those of the other alkali metals but much less stable.

Recently evidence has been obtained for the existence of a lamellar compound of sodium with graphite of composition $C_{60}Na$–$C_{68}Na$, probably $C_{64}Na$. The compound is very similar to the parent graphite, but has a deep violet tinge. It is prepared by heating powdered graphite with about 3% of sodium of commercial purity, filtered through sintered glass at about 150° C. The reaction is carried out in a helium atmosphere containing less than 20p.p.m. of oxygen in a 'glove box', with stirring for one hour at about 400° C. The experimental conditions are not critical. The most sharply defined *X*-ray diffraction pattern is obtained when the product is made from highly crystalline, *i.e.* purified, natural graphite, and definition is also improved by prolonged heating at 400° C. The sodium atoms appear to lie in interstitial planes separated by eight carbon layers. At every eighth layer the spacing is increased from 3·35A. to 4·6A., which is consistent with the atomic diameters of sodium and carbon.[188]

Sodium wets graphite above 450° C. and when a graphite rod is immersed in the molten metal in a helium atmosphere, with about 6in. of the rod above the surface, about 60% of the voids in the graphite are filled with sodium, presumably by capillary action. At 550° C. and after 50 hours, all the voids are filled. Since sodium has a relatively high thermal conductivity, hot graphite immersed in cooler sodium may be fractured by thermal shock. In circulating non-isothermal systems where sodium is in contact with graphite, there is a mass transfer of carbon from the hot regions and a deposition in the colder regions. In static systems liquid sodium corrodes graphite at insignificant rates unless a 'sink' is available to remove the carbon that enters the sodium. Stainless steel at temperatures above 500° C. acts as a 'sink'. No quantita-

The measured velocity constants refer to the primary reaction: R.N=O + Na R-N- + NaO. The high collision yields are about 1 in 10.[178]

tive data are available for the solubility of carbon in sodium.[33] The literature on the reactions of sodium with graphite has been reviewed by Monet.[189]

Other forms of carbon such as soot or lampblack are attacked by sodium at elevated temperatures, and Table XI gives the amount of shortening which occurs when small sticks of retort carbon are heated for 1·5min. in sodium vapour at various temperatures. Probably a solid solution of the alkali metal in carbon is formed. Carbon powder accumulating on the surface of the evaporating metal in contact with air sometimes ignites with violent explosions.[190]

Petroleum coke, lampblack and metallurgical coke, passing a 200 mesh

TABLE XI. - SHORTENING OF CARBON RODS HEATED IN SODIUM VAPOUR

400-500	No change
520-575	Very little change
575-675	0·2
740-825	0·6
840-915	1·0

sieve, have been heated with sodium at 900°C. in an evacuated Monel tube closed at its cooled end with a plug of sodium in order that the pressure of sodium vapour can be built up. Petroleum coke and lampblack yield considerable quantities of sodium carbide, but no carbide can be detected when metallurgical coke is used. The reaction is not catalyzed by iron.[161]

Sodium and potassium residues in large amounts can be disposed of by burning in an open fire of charcoal or coke stirred with an iron rod. On cooling, the residue, largely sodium carbonate, can be thrown into large containers of water.[143]

The reactions of the steam-carbon system have been studied by a static method at 750°C. with extracted coconut charcoal to which various catalysts have been added. Sodium catalyzes this reaction and also the carbon dioxide reaction. The oxidation of carbon monoxide by steam is also enhanced by sodium.[191]

The formation of sodium carbonyl directly from sodium and carbon monoxide has not been reported.[33] A lilac coloured solid, NaCO, is, however, formed when carbon monoxide is led into a liquid ammonia solution of sodium at -50°C. It decomposes at 90°C.: $4NaCO \rightarrow Na_2CO_3 + Na_2O + 3C$. When heated in air, sodium carbonyl explodes.[143]

Sodium can be made to react with carbon monoxide to form sodium carbide and carbonate: $4Na + 3CO \rightarrow Na_2C_2 + Na_2CO_3$; the reaction is endothermic and the highest yield of carbide is obtained when the reaction temperature is in the range 625-780°C. Under optimum conditions the product is substantially white, but in some cases it may be grey or black owing to a certain amount of decomposition of carbon monoxide to carbon. The sodium is contained in small steel containers made to withstand pressure and carbon monoxide is led in while the containers are shaken in an electric furnace at 625° to 780°C. The product is somewhat fluid at the reaction temperature but sets to a hard, dense material on the cooled surface of the apparatus. The product contains 20 to 39·76wt.-% of sodium carbide, the rest being largely sodium carbonate with minor amounts of sodium or sodium monoxide and traces of sodium cyanide. A more economic process is to use the old Deville process to obtain sodium from sodium carbonate and to allow the sodium vapour and carbon monoxide to react together: $2Na_2CO_3 + 4C \rightarrow 4Na + 6CO$; $4Na + 3CO \rightarrow Na_2CO_3 + Na_2C_2$. The reaction: $2CO \rightleftharpoons CO_2 + C$, also occurs to some extent. Sodium carbonate and finely divided petroleum coke are heated together at 1050° to 1200°C. and the sodium vapour and carbon monoxide formed in the reaction are cooled to 625° to 780°C. by bringing the gas mixture into contact with a mass of steel bodies, each having a mass equal to that of a steel sphere of 0·2 to 2in. in diameter. The condensed material is in the form of a pasty solid, and on cooling to room temperature a hard, dense, enamel-like product is obtained which is very difficult to remove. The product may by treated *in situ* with water to give acetylene.[192]

Sodium vapour, carbon monoxide and nitrogen when passed through a 60-watt lamp, operating at its normal temperature, react to form sodium cyanide: $3Na + CO + N \rightarrow NaCN + Na_2O$. About 0·5g. of sodium cyanide is formed in 100 hours.[193]

The slow oxidation of carbon monoxide by nitrous oxide is catalyzed by performing the reaction in vessels coated with sodium chloride or bromide. Simultaneous emission of the sodium resonance lines is also observed and the following reactions have been suggested, although the mechanism of the formation of sodium atoms from the halides is uncertain: $Na + N_2O \rightarrow NaO + N_2$; $NaO + CO \rightarrow Na^* + CO_2$; $Na^* \rightarrow Na + h\nu$. This mechanism is confirmed as follows. Sodium vapour at 300° C. is led into a reaction chamber containing nitrous oxide at 350° to 375° C. and the products are condensed and analyzed for carbon dioxide and nitrous oxide: the results obtained in 1 to 1·5 hours using nitrogen as carrier gas at a velocity of $1{\cdot}7 \times 10^5$ mole/sec. are given in Table XII.

TABLE XII. - REACTION OF SODIUM VAPOUR WITH CARBON MONOXIDE AND NITROUS OXIDE AT 350° TO 375° C.

375	0·014	4·29	2·14	1·07	42	59	32	30

The slow nitrous oxide/carbon monoxide reaction does not excite the metal lines when the vessels are coated with potassium chloride or sodium iodide but the red lithium lines are briefly excited when the coating is lithium chloride.[194]

The reactions of metal carbonyls with sodium in liquid ammonia solutions are referred to elsewhere (see page 519).

The carbonyl $[Co(CO)_4]_2$ reacts with sodium amalgam to give the sodium salt; $Na[Co(CO)_4]$.[195]

An explosive reaction occurs when sodium and solid carbon dioxide are brought together by impact.[143,196-198] At room temperature there is apparently no reaction between sodium and carbon dioxide,[2,143] but at red heat free carbon, sodium monoxide and sodium carbonate are formed.[143] It would appear from the following experiment that although sodium burning freely in air burns with increased vigour when the air is replaced by carbon dioxide, the gas can be used to extinguish solvent fires in their initial stages even when sodium is present. Acetone was poured into a metal tray and sliced sodium was distributed on the tray. On ignition the solvent burned while the sodium melted without burning. When the maximum temperature was apparently reached, carbon dioxide was applied and the solvent fire was extinguished without ignition of the sodium. The sodium appears to be protected by a blanket of solvent vapour from the intense heat required for its ignition.[199]

According to Haupt[200] sodium is converted quantitatively into sodium oxalate by injecting molten sodium at 150° to 200° C. and carbon dioxide at 360° to 400° C. and at 0·5atm. into a sheet iron chamber. The carbon dioxide is present in excess and unchanged gas escapes through a vent and is recycled. The sodium oxalate formed falls to the bottom of the chamber: $2Na + 2CO_2 \rightarrow Na_2C_2O_4$. The sodium is melted under a mineral oil or in a nitrogen atmosphere. Reactions between carbonyl compounds and amalgams have been studied by Henglein and Sontheimer.[201] The conversion of carbon dioxide and sodium amalgam to sodium oxalate is about 80% complete at room temperature and decreases with increasing temperature. A relation between yield and half-wave potential of the amalgam is indicated by the following data.

Amalgam	Half-wave potential	Yield % at t°C.				
		20°	100°	200°	225°	250°
Zn	−1·06V.	–	No reaction			
Mn	−1·55	–	Practically no reaction			
Na	−2·15	75	55	47	–	41
K	−2·17	25	60	72	68	61
Ca	−2·23	4	–	–	–	–
Li	−2·31	0·1	–	–	–	4·5

Hohn, Fitzer and Nedwed[202] report that pure carbon dioxide and sodium amalgam give a 100% conversion to oxalate. With 0·02–0·2% sodium amalgam the reaction velocity is practically independent of concentration; the conversion rate is increased by stirring although the total yield is unchanged; the reaction rate seems to increase with decreasing temperature. Water vapour present in the carbon dioxide causes the formation of sodium carbonate or bicarbonate or both these salts as well as some carbon monoxide; oxygen gives some peroxide while hydrogen and nitrogen do not affect the net result. An example given in a patent[27] states that the amalgam is violently agitated during the process so that the amalgam surface is continuously destroyed; sodium oxalate containing 0·3% of sodium carbonate is produced from sodium amalgam and dry carbon dioxide. Thermodynamic calculations indicate that the amalgams of sodium, potassium, lithium, calcium, barium, manganese and zinc should react with carbon dioxide to give oxalates, whereas those of cadmium and copper should not. Only the amalgams of lithium, calcium, barium, manganese and zinc should reduce carbon dioxide to carbon monoxide. The effects of sodium concentration and of temperature change have been reported[202] but the effect of motion of the amalgam is greater than had been supposed. The reaction rate increases linearly with increase of carbon dioxide pressure. If the sodium content is greater than 0·007% and the carbon dioxide pressure greater than one atmosphere, the regeneration of the surface of the amalgam determines the rate and not a diffusion process. The amount of oxalate formed decreases as the amount of air added is increased and with 50% of air no oxalate is formed[203] (see also [204,205]).

An amalgam containing 0·1% of sodium is placed in a gas-tight chamber in which brushes or scrapers are rotated at high speed, e.g. 1000 r.p.m. in contact with the walls of the vessel. The amalgam surface, rapidly and continuously disrupted in this way, is allowed to react with dry carbon dioxide at 20°C. to give an almost 100% yield of sodium oxalate with about 0·3% of sodium carbonate. At the completion of the test freshly boiled distilled water is added with stirring and without entry of air. The aqueous sodium oxalate and mercury separate smoothly into distinct layers.[29]

An account of the technical and economic aspects of the use of sodium amalgams for the production of sodium compounds including sodium oxalate is given by Nicolai.[30] Sodium amalgam reacts with carbon dioxide in aqueous solution to form sodium formate and sodium hydroxide: $2Na + CO_2 + H_2O \rightarrow HCOONa + NaOH$.[30]

Atomic reactions of sodium with carbon dioxide have been studied at 260° C. in the presence of an inert carrier gas such as nitrogen at a pressure of 3 to 13mm. Hg. No reaction occurs.[41]

Finely dispersed sodium, produced during the electrolysis of aluminium oxide dissolved in cryolite using carbon electrodes, may reduce carbon dioxide, formed by the action of oxygen on the carbon anode, to carbon monoxide.[206]

An abrasive crystalline carbon is said to be produced by the action of sodium on carbon dioxide or carbon monoxide at 50–100atm. pressure and 1000° to 1500°C.[207]

The reaction of sodium atoms with phosgene has been studied by the diffusion flame method. At a temperature of 270°C., using a partial pressure of sodium vapour about 3×10^{-3}mm., and a partial pressure of the inert gas about 1 to 10mm., the reaction velocity constant is 856c.c.mole^{-1}sec.$^{-1}$ $\times 10^{-11}$ and the collision number 7. The luminescence which accompanies the reaction is due to the excitation of the *D*-line of sodium. The following mechanism is suggested: $Na + COCl_2 \rightarrow NaCl + COCl$; $Na + COCl \rightarrow NaCl^* + Na$; $NaCl^* + Na \rightarrow NaCl + Na + h\nu$.[158]

Molten sodium has been said to react with liquid carbon disulphide forming sodium sulphide[33] but another experiment indicates that no reaction occurs.[208]

Reactions of carbon disulphide with liquid ammonia solutions of sodium are described on page 520.

The action of sodium amalgam on carbon disulphide appears to be complicated.[208,209] In methylation experiments 1·5kg. of sodium amalgam was boiled with 450c.c. of carbon disulphide and, after removal of carbon disulphide, 2·5 l. of 90% alcohol was added to give a dark red solution through which was passed 80 l. of methyl chloride. The mixture was heated for 12hr. on a water bath, filtered hot to remove sodium chloride and evaporated to half its volume. The products were: dimethyldithiondithioloxalate or perthio-oxalate $(CS_2Me)_2$, and the compounds $CH_3OCS_2CH_3$ and $(CH_3)_2CS_3$, with some tetrakis(methylmercapto)ethylene. The formation of the compound $CH_3OCS_2CH_3$ is considered to be due to a side reaction.[208]

The diffusion flame technique has been used to study the reaction between sodium atoms and carbon disulphide vapour. At 270°C., with a partial pressure of sodium of 3×10^{-3}mm.Hg and a pressure of 1 to 10mm. for the inert carrier gas, the reaction velocity constant is about 0·0306c.c.mole^{-1}sec.$^{-1}$ $\times 10^{-11}$ and the collision number 200 to 500. The reaction is thus very slow. The product, CS_2Na, is probably formed by a third body collision mechanism. No chemiluminescence is observed.[158]

When ethylene is passed through a tube containing liquid sodium at 150°C. the ethylene is polymerized to a colourless liquid and sodium converted to a white brittle mass of sodium ethylene carbide. The accumulation of the sodium reaction product, which is inert towards ethylene, prevents further reaction. At higher temperatures the polymerization is accompanied by some decomposition of ethylene to acetylene and hydrogen, which react with sodium to form sodium acetylide, hydride and carbide. Free carbon and hydrogen are produced by the decomposition of acetylene; hydrogenation of ethylene and of the $:CH_2$ and $\vdots CH$ groups, formed by the splitting of ethylene or acetylene between the carbon atoms, accounts for the presence of small amounts of ethane and methane respectively in the exit gases.

The vapour pressure of sodium at 400°C. is sufficiently high for it to distil over and condense on the walls of the tube beyond the heating unit. The above reactions are thus summarized: $xC_2H_4 \rightarrow (C_2H_4)_x$, (150°C.); $C_2H_4 \rightarrow C_2H_2 + H_2$ (200°C.); $2Na + H_2 \rightarrow 2NaH$ (200°C.); $Na + C_2H_2 \rightarrow C_2HNa + 0{\cdot}5H_2$ (200°C.); $2C_2HNa \rightarrow Na_2C_2 + C_2H_2$ (210°C.); $C_2H_2 \rightarrow 2C + H_2$ (>200°C.). The results of experiments carried out in the temperature range 150° to 550° in the presence of sodium are given in Table XIII.

The low yield of acetylene at 550°C. is due to the reaction of sodium with acetylene to form acetylides and to the decomposition of acetylene to carbon and hydrogen.[210]

The effect of ethylene on the quenching of sodium resonance radiation, the rate of polymerization of ethylene in the presence and absence of such radiation and the effect of sodium surfaces or sodium vapour on the thermal

polymerization of ethylene over a somewhat higher temperature range, have been investigated. Sodium metal is distilled into a cylindrical tube, previously evacuated at high temperatures, and is deposited on the walls as a bright metallic mirror. The tube is heated to the reaction temperature and illuminated with a Zeiss sodium lamp. The admission of ethylene at a pressure as low as 5mm. suffices to extinguish the visible fluorescence *i.e.* the energy of the excited sodium atoms is transferred to ethylene by collision. The results of tests carried out between 132° and 255°C. are shown in Table XIV.[213]

TABLE XIV. - PHOTOSENSITIZED POLYMERIZATION OF ETHYLENE BY SODIUM RESONANCE RADIATION

Temp. °C.	Pressure mm./25°C.	Time of illumination, h.	ΔP mm.

At least 48kg.-cal. per mole are transferred to the ethylene molecules by collision with excited sodium atoms and although this is a larger amount of energy than that required as activation energy in the thermal polymerization process, 35 to 42kg.-cal. at 350° to 400°C.,[211,212] no observable polymerization occurs at 132° to 255°C. by sodium radiation.

The results of experiments carried out on the thermal polymerization of ethylene with and without sodium are shown in Table XV.[213]

TABLE XV. - THERMAL POLYMERIZATION OF ETHYLENE IN PYREX VESSELS WITH AND WITHOUT A COATING OF SODIUM

No. of expt.	Temp. °C.	Pressure mm.	ΔP mm.	Δt h	$\Delta P/\Delta t$	Remarks

9	255	181	23·0	232	0·1	Sodium present

The presence of sodium obviously catalyzes the polymerization; illumination with sodium resonance radiation in the above temperature range again produces no noticeable acceleration. The activation energy deduced from experiments 6, 7 and 8 is $E = 20$ kg.-cal., and from experiments 7 and 9 $E = 17$ kg.-cal. These values are lower than those of Pease[211] and Storch.[212]

The efficiency of resonance radiation with mercury at room temperature and cadmium at 200°C. in the acceleration of the polymerization of ethylene is associated with their ability to form free radicals which are efficient agents in the initiation of a polymerization chain. The mechanism of the thermal polymerization process is still obscure.[213]

Sodium reacts with acetylene to form acetylides and hydrogen: $2Na + C_2H_2 \rightarrow Na_2C_2 + H_2$; $\Delta H^\circ_{298} = -8{\cdot}396$ kg.-cal./mole.[33,214,215]

The dissociation pressures of sodium acetylide have been measured between 100° and 183°C., the following equation expresses the experimental results: $\log_{10}P(\text{mm.}) = 8{\cdot}538 - 2749/T$. The heat of dissociation deduced from this equation is +12·6 kg.-cal., which is higher than that obtained from the standard heats of formation of the reactants and products at 18°C.: $2NaC_2H \rightleftharpoons Na_2C_2 + C_2H_2$; $\Delta H^\circ_{291} = 8{\cdot}2$ kg.-cal.[216]
2(25·1) (4·1) (54·3)

Sodium reacts with acetylene in liquid ammonia solution to form sodium acetylide: $C_2H_2 + Na \rightarrow CHCNa + 0{\cdot}5H_2$ (see page 522).

Atomic reactions of sodium with cyanogen and with cyanogen chloride and bromide have been investigated by the diffusion flame method. Although the reaction with cyanogen is exothermic, the collision yield is only 1 in 15,000 at 300°C. and 500°C.[38,97] Cyanogen chloride and bromide react to give sodium halide rather than the cyanide. Curry and Polanyi have shown that the primary reactions are: $Na + CNCl(Br) \begin{array}{l} \rightarrow NaCl(Br) + CN \\ \rightarrow NaCN + Cl(Br) \end{array}$ and that the ratio of NaCN: NaCl is not greater than 1:50 at a reaction temperature of 270° to 400°C. The secondary reaction, $Cl + Na_2 \rightarrow NaCl^* + Na$, produces sodium chloride molecules which carry most of the energy of the reaction and on collision with other sodium atoms excite them to emission of the D-line.[217]

Anhydrous hydrogen cyanide reacts with sodium amalgam in the presence of a solvent or suspension medium to form sodium cyanide. Alternatively the amalgam can be converted to alkoxide which is then used to react with hydrogen cyanide.[219]

The velocity constants for the reactions of sodium vapour with cyanogen fluoride, chloride and bromide as measured by the diffusion flame method of Hartel and Polanyi are in the ratio of 1:1·7:120.[218]

Fatty esters treated with sodium in the presence of a reducing alcohol such as *iso*butyl alcohol are converted into alkoxides which react with urea on refluxing at a temperature below 200°C. to yield a precipitate of sodium cyanate: $RONa + NH_2CONH_2 \rightarrow ROH + NaOCN + NH_3$.[220]

The oxide of cobalt is reduced by sodium to metallic cobalt, 97% of which remains in the alpha form at room temperature.[221]

The reduction of the dioxides of thorium, zirconium and titanium by sodium or calcium or a mixture of the two has been described by Ruff and Brintzinger.[222] The reaction is carried out in a wrought iron bomb and the results obtained for the reduction of thorium dioxide are given in Table XVI; the percentage of thorium in the product is obtained by measuring the volume of hydrogen evolved on treatment with hydrochloric acid: $Th + 4HCl \rightarrow ThCl_4 + 2H_2$. No reaction occurs below the boiling point of sodium in the absence of calcium, *i.e.* with 100% sodium. Optimum results are obtained by using 30% of sodium and 70% of calcium as reducing agent. A 90% yield of thorium of 96% purity has thus been obtained.

The reduction of zirconium dioxide has been brought about in a similar way. Zirconium in the product is determined by measuring the hydrogen evolved on treatment with hydrogen fluoride: $Zr + 4HF \rightarrow ZrF_4 + 2H_2$.

The results of three experiments are given in Table XVII.

TABLE XVII. - REDUCTION OF ZIRCONIUM DIOXIDE WITH SODIUM AND CALCIUM

A mixture of sodium and calcium containing about 30% of sodium is a more efficient reducing agent than either calcium or sodium alone.

Titanium dioxide has been reduced to the metal under similar conditions, as detailed in Table XVIII. No reduction is observed with sodium alone nor is the efficiency of the calcium reduction appreciably increased by the addition of sodium. The percentage of titanium in the product has been determined by measuring the volume of hydrogen evolved on treatment with hydrochloric acid: $2Ti + 6HCl \rightarrow 2TiCl_3 + 3H_2$.

Zirconium and similar refractory metals are obtained by heating together the oxide, ZrO_2, an alkali metal such as sodium and an alkali metal halide the base of which is different from the alkali metal used. Oxygen and nitrogen must be absent.[223]

Titanium and zirconium oxides are also reduced to the metals by heating with one or more alkali metals and calcium chloride.[224]

The reduction of chromium trioxide by sodium vapour is brought about by smelting a mixture of chromium trioxide and an oxygen compound of sodium, such as sodium carbonate, with carbon to liberate and volatilize sodium which reduces the oxide to chromium.[225]

The reduction of metallic oxides by sodium vapour is achieved by allowing sodium vapour to react with the oxide in the presence of coke and nitrogen or a carbonaceous and nitrogenous material, when the heat generated by the formation of sodium cyanide is used to bring about the reduction.[226]

Sodium reduces iron oxide below 1200°C. at atmospheric pressure; iron reduces sodium oxide at 550°C.[227]

High-surface sodium, deposited on a carrier, reduces metallic oxides to the metals. Dry zinc oxide is placed in a flask, the air of which is displaced with dry nitrogen, and sodium is added with stirring at 130°C. As soon as the sodium is dispersed over the surface of the oxide, the temperature is raised and although reduction begins at 130°C. to 150°C. it is necessary to heat at 230°C. to 300°C. to complete the reaction. The product is a mixture of colloidal zinc, sodium monoxide and unchanged zinc oxide. The finely divided zinc is isolated by washing with water. Metals prepared in this way are of colloidal dimensions and very reactive; when exposed to air they are pyrophoric and should therefore be used as formed in a continuous or semi-continuous process. Experimental data for iron, zinc and nickel oxides are given in Table XIX.[64]

TABLE XIX. - REDUCTION OF IRON, ZINC AND NICKEL OXIDES BY HIGH-SURFACE SODIUM

Compound	Sodium carrier	Reduction temp. °C.	Yield of metal %
Fe_2O_3	NaCl	100-200	>90
ZnO	ZnO	230-300	80-95
NiO	NaCl	300	-

Halla and Tompa have studied the system sodium/sodium hydroxide by means of thermal analysis, *X*-ray examination and chemical analysis.

Caustic soda is melted in a nickel crucible in an atmosphere of dry nitrogen freed from carbon dioxide, and the temperature of the melt kept at 450°C. for 3-4hr. to remove moisture. Small cubes of freshly cut sodium are thrown into the melt and the crucible quickly closed. Thorough mixing of the components is achieved by rotating the crucible about a horizontal axis for 24hr. at 400°C.; the crucible is then placed in a vertical position and thermal data collected during the cooling stage. When completely cold, the crucible is opened, and a drilling of the solidified melt quickly removed for chemical analysis. The melt, which is dark green, yields on solidification a homogeneous yellowish white crystalline aggregate which is sensitive to daylight, on exposure to which it becomes a green to greyish blue colour. Pure sodium hydride behaves in a similar way on exposure to daylight. *X*-Ray examination of the solidified melt shows the presence of sodium monoxide, sodium hydride and sodium hydroxide.

The reaction which occurs when sodium is added to sodium hydroxide under the above conditions is given by the equation: $2Na + NaOH \rightarrow Na_2O + NaH$.

In the course of this work the m.p. of pure sodium hydroxide has been shown to be 327·6 ± 0·9°C. and the effect of water and sodium carbonate on the melting point determined; $t = 327{\cdot}6 - 0{\cdot}196p - 0{\cdot}0011p^2 - 0{\cdot}30w$, where p is the sodium carbonate content expressed as g. per 1000g. of melt, and w is the water content.

The composition of the melt has been determined as follows: a known weight is dissolved in water and a portion of the standard solution titrated with 0·1N. hydrochloric acid in the presence of methyl-orange. Another portion is treated with barium chloride and titrated with 0·1N. oxalic acid with phenolphthalein as indicator. The difference between the two titrations is used to calculate the sodium carbonate content. A portion of the solidified melt is treated with water and the volume of hydrogen evolved is measured to determine the sodium hydride content. If 1g. of melt contains xg. of sodium carbonate and yg. of sodium hydride and produces zg. of sodium hydroxide in solution in water, then the weight of sodium monoxide $= \frac{62}{18}[z - (1 - x) - \frac{2}{3}y]$.

In Table XX the solidification temperatures in column 6 have been corrected for sodium carbonate content.

TABLE XX. - ARREST POINTS IN THE SYSTEM SODIUM-SODIUM HYDROXIDE

Since the molecular ratio of sodium hydride to sodium monoxide in the melt should be 1·0, it is apparent from the figures given in Table XX that the apparatus was not completely gas-tight (test 9, 0·88, test 14, 0·65) and that in some cases (tests 11, 27, 35, 37) there was an error in the estimation of hydride and oxide content.[228]

The action of sodium on sodium hydroxide has been investigated more recently by Williams[70] by heating the mixture in stainless steel vessels up to 600° C. or in nickel vessels up to 700° C.

If the components are heated in an evacuated system at temperatures up to 385° C., hydrogen is evolved according to the dissociation pressure of sodium hydride until all the sodium hydroxide has been converted into sodium monoxide.

When the components are heated in a closed system above 385° C., an equilibrium is established which does not correspond to the dissociation pressure diagram for sodium hydride, and this new equilibrium appears to be related to the solubility of the reaction products in sodium and sodium hydroxide. The system appears to be influenced by a number of simultaneous reactions: $2Na + NaOH \rightleftharpoons Na_2O + NaH$; $NaH \rightleftharpoons Na + 0{\cdot}5H_2$; $H_2 + Na_2O \rightleftharpoons NaOH + NaH$.

Fig. 5 shows a typical sodium-sodium hydroxide reaction curve obtained by plotting the pressure of hydrogen evolved against the reaction temperature. The dome shaped plateau and the reabsorption dip occur at the same pressures and temperatures even when the ratio of sodium to sodium hydroxide is varied from 1:4 to 8:1. When the system at about 550°C. is cooled, the cooling curve as shown in Fig. 6 returns linearly until a temperature of about 385°C. is reached; it then proceeds along the heating curve. The hump of the heating curve is therefore a quasi-equilibrium region where two or more competing reactions are taking place.

The rise in pressure beyond 600° C. shown in Fig. 5 is due to attack on the

⊙ Heating curve; ● Cooling curve.

stainless steel pot and to a further direct release of hydrogen from sodium hydride.

The presence of an inert gas depresses the dissociation of sodium hydride in the sodium–sodium hydroxide reaction as may be seen from Fig. 7.

The system sodium–hydrogen–sodium hydroxide–sodium monoxide has also been studied by Klemenc and Svetlik. The reduction of sodium monoxide with hydrogen begins at 110°. A method is also given for the determination of sodium hydride formed in the system.[229]

Sodium hydroxide, sodium oxide, sodium, sodium hydride and hydrogen are obtained as an equilibrium mixture when sodium hydride is dissolved in molten sodium hydroxide. Where there is a gaseous phase, hydrogen, and only one condensed phase, the system is defined by the temperature, pressure and one composition variable. The equilibrium hydrogen pressure has been determined as a function of the composition of the condensed phase or phases for equilibrium mixtures with original compositions of 2·5–97·5, 5·0–95·0, 10·0–90·0 and 20–80mole-% of sodium hydride in sodium hydroxide at 600°, 700° and 800°C. The equilibrium hydrogen pressure-composition isothermals obtained by removing measured increments of hydrogen have been reproduced by allowing hydrogen to be reabsorbed; results for the 5·0mole-% sodium hydride mixture have been duplicated by starting with an equivalent quantity of sodium in sodium hydroxide and allowing the mixture to react with measured increments of hydrogen.[230]

The estimation of hydrogen in sodium hydroxide by reduction with sodium at 700°C. has been described by Pepkowitz and Proud[231] to demonstrate a micromethod for the determination of hydrogen in its compounds. Typical results are given in Table XXI.

Sodium vapour passed in counter-current through molten potassium hydroxide under reduced pressure reduces the hydroxide to potassium; the resultant metal vapours condense to form sodium-potassium alloys from which potassium may be isolated by fractionation.[232]

The system $\mathrm{Na} + \mathrm{KOH} \rightleftharpoons \mathrm{K} + \mathrm{NaOH}$ has been investigated by Rinck.[233] The materials employed are described as pure industrial products; the hydroxide was, however, subjected to a prolonged fusion in a silver capsule to remove moisture before use.

The required quantities were introduced into a well dried steel tube, which was sealed and placed in an already heated furnace. When a temperature of about 400° C. was attained, the mixture was energetically shaken for 20 to 30 min. in a horizontal position by a mechanical device and the tube then placed in a vertical position for the same length of time to facilitate separation of the two liquid phases, the light layer of sodium–potassium alloy and the heavier layer of the two hydroxides. The system was then rapidly chilled by submerging the tube in cold water. The stopper was sawn off and the liquid sodium-potassium alloy poured in small amounts at a time into absolute alcohol; when the reaction was complete, water was added and the solution analyzed for total alkalinity and for potassium by the perchlorate method while sodium was calculated by difference.

The mixed hydroxides were contaminated with the liquid phase but measurement of the hydrogen evolved on treatment with water gave the necessary data for calculation of the amount present. The solution was diluted and tested for total alkalinity and potassium, sodium being determined by difference.

The results are given in Table XXII where the equilibrium constant C has been calculated on the assumption that the 'perfect' law of mass action holds. Lorentz's law of mass action, governing condensed systems and based on an equation of state analogous to that of van der Waals has been used to calculate the equilibrium constant, K. The constant C is found to vary from 0·77 to 0·31 but K also varies and in this case from 0·644 to 0·238.

Slight carbonation always occurs when the alkali hydroxides are manipulated in air, so that the results obtained by Rinck refer to the equilibrium between potassium, sodium and very dilute solutions of the metal carbonates in caustic alkalis. The concentration of the carbonates can vary from one experiment to another so that the equilibrium constant must also vary. The main reaction, $Na + KOH \rightleftharpoons NaOH + K$, is therefore accompanied by the secondary reaction, $2Na + K_2CO_3 \rightleftharpoons Na_2CO_3 + 2K$. Also, analysis of the hydroxide phase includes an appreciable error due to the conversion of some of the alkali metal to oxide, hydroxide and carbonate and to the solubility of the alkali metals in their compounds.

Rinck concludes that there is no reason to suppose that the above equilibrium does not obey the 'perfect' law of mass action and he gives a value of 0·50 for the equilibrium constant $C = [Na][KOH]/[K][NaOH]$ at 400° to 700°C. During this work the densities of sodium and potassium were found to be: $d_t = 0{\cdot}9385 - 0{\cdot}000260(t - 96{\cdot}5)$ for sodium and $d_t = 0{\cdot}826 - 0{\cdot}000222(t - 62{\cdot}5)$ for potassium.[233]

Halla and Tompa show that the upper limit for the equilibrium constant at 400° C. for the reaction: $K_2O + Na \rightleftharpoons Na_2O + K$ is 0·434.[234]

The reaction between fused sodium and potassium and their fluorides has been studied by Rinck at 1000° C. Preliminary experiments show that at this temperature steel is badly attacked but thick walled nickel tubes are satisfactory. The fluoride is dehydrated before use and although equilibrium at 1000° C. is reached in about 2-3min., shaking for 10 min. before the tube is placed in a vertical position allows the light metal phase and the heavier fluoride phase to separate. The system is then preserved by rapidly chilling and the metal and fluoride phases analyzed, the former by the method already described in the metal–hydroxide reaction above and the latter as follows. Since the fluoride phase always contains some of the alloy, the total alkalinity of its aqueous solution is determined and expressed as potassium fluoride; potassium is determined by the perchlorate method and expressed as potassium fluoride; total fluorine is estimated as calcium fluoride and from these determinations the amounts of sodium fluoride and potassium fluoride can be obtained. The experimental figures are very similar to those calculated from the composition of the starting materials and that of the metal phase, from which it is concluded that the metals dissolve in the mixed fluorides in the same ratio as they are alloyed in the metallic phase. The experimental results given in Table XXIII[233] include also those for four ternary mixtures, and the average value for the equilibrium constant $C = [\mathrm{Na}][\mathrm{KF}]/[\mathrm{K}][\mathrm{NaF}] = 0{\cdot}29$ at 1000° C.[233,235]

Equilibria between sodium and potassium and their chlorides in the fused state have been studied by Jellinek and Tomoff.[236] The alkali metal is dissolved in molten lead and the sodium-lead alloys heated at 800°C. with potassium chloride in a refractory crucible. The proportions of the reactants are varied and the product is analyzed at intervals of 6min. For a given mixture the ratio of sodium to potassium in the solid phase is found to be constant. The reaction, $\mathrm{Na} + \mathrm{KCl} \rightleftharpoons \mathrm{K} + \mathrm{NaCl}$ is shown to be an equilibrium reaction governed by the law of mass action such that $\frac{[\mathrm{Na}]}{[\mathrm{K}]}\cdot\frac{[\mathrm{KCl}]}{[\mathrm{NaCl}]} = 12{\cdot}2$ (the average of 10·4, 11·4 and 14·8) at 800°C. The concentrations of the alkali metals,

[Na], [K] are expressed as the number of atoms per 100 atoms of alkali metal dissolved in the lead, and [NaCl], [KCl], as the number of molecules of each chloride per 100 molecules of total chloride in the salt phase. By carrying out the reaction in this manner, the alkali metal–lead alloy, which is very heavy, settles to the bottom leaving the mixture of fused chlorides at the top of the crucible.

Jellinek and Czerwinski[237] have also studied the above reaction. Salt mixtures of definite composition are fused above molten lead (which serves as a cathode) in such amounts that on electrolysis, using a carbon rod as anode, no appreciable change takes place in the salt mixture owing to the deposition of metal. The lead–sodium alloy and potassium chloride are then allowed to react at 1000°C. The equilibrium is shown to conform to the law of mass action and $\frac{[Na][KCl]}{[K][NaCl]}$ is 11·1 at 1000°C. (average of 13·0, 11·2 and 9·0) (see also Fig. 8 page 486). Hackspill and Rinck[233,238] in their work on the equilibrium reaction: $Na + KCl \rightleftharpoons K + NaCl$, have dispensed with the solvent, molten lead, and heated the components at 900°C. in a sealed iron tube which is shaken vigorously in a horizontal position by a mechanical device. Although equilibrium is attained in a short time, the mixture is heated and shaken for 30min. after which it is placed vertically for another 30min. to facilitate the separation of the liquid phases. The system is rapidly chilled and on opening the tube the liquid metal alloy phase is found on the top and the halide phase at the bottom. The alloy phase is analyzed for total alkalinity and for potassium.

Although the separation of the two phases is generally satisfactory, the halide ingot still contains a certain amount of the alkali metals in the form of droplets of alloy in the crevices of the salt; this alloy has the composition of the metallic phase. A metallic mist is also uniformly distributed throughout the mass. Fused alkali chlorides dissolve appreciable quantities of potassium and sodium and on solidification the metals separate out and remain dispersed.

About 1g. of the salt is powdered and treated with absolute alcohol to dissolve out the metals, and when the hydrogen evolution has ceased, the mass is washed with alcohol and dissolved in water. The total alkalinity is determined, and assuming that the alkalinity is due to the presence of a mixture of sodium and potassium of the same composition as the metallic phase, the amount of potassium to which the hydroxide is equivalent can be calculated. The total potassium is determined by the perchlorate method and the result calculated as potassium chloride from which the amount corresponding to the metallic potassium dissolved is deducted. The total chloride is found and also the sodium by the uranyl acetate method.

The experimental results are given in Table XXIV.

The equilibrium constant C is calculated from the 'perfect' law of mass action, K from Lorentz's law of mass action governing condensed systems and based on an equation of state analogous to that of van der Waals.

The reaction $Na + KCl \rightleftharpoons K + NaCl - 6{\cdot}7$ kg.-cal. is endothermic at ordinary temperatures; the calculated value at 900°C. is –8 kg.-cal. Reduction in temperature should therefore favour the formation of sodium and potassium chloride with the disappearance of potassium and sodium chloride and this is confirmed by the finding that the equilibrium constant C at 800°C. is 14 whereas at 900°C. it is 11·5. Since the equilibrium constant K varies more than the constant C it is considered that within experimental error the equilibrium $Na + KCl \rightleftharpoons K + NaCl$ is governed by the 'perfect' law of mass action.

Potassium or potassium-sodium alloys are formed by continuously passing

molten potassium chloride into a reaction column at atmospheric pressure along with sodium vapour. The potassium vapour or potassium–sodium vapour rises and passes into a condensation chamber from which the metal or alloy is removed in the solid state. The sodium-rich slag is removed from the bottom of the reaction chamber and recycled to the sodium vaporizer.[239]

The equilibrium in the fused state between sodium, potassium and their bromides has been investigated by Rinck[233,240] at 800°C. The bromides are first dehydrated by fusion in a platinum crucible and the procedure is then similar to that employed for sodium, potassium and their hydroxides (see page 478). As may be seen from Table XXV, the equilibrium constant *C*, calculated from the simple law of mass action, fluctuates irregularly about an average value of 28·9, the deviation being less than 20%, whereas the equilibrium constant *K*, calculated from Lorentz's law governing condensed systems, varies about an average value of 13·1 with a deviation exceeding 25%. Rinck considers that the system is best represented by the simple mass action law and that the equilibrium constant at 800°C. $= [Na][KBr]/[K][NaBr] = 28{\cdot}9$.

Equimolecular amounts of sodium and potassium iodide have been heated together at 725°C. in a sealed tube in a rotary furnace and the reaction products rapidly chilled and analyzed. The ratio of sodium to potassium in the metallic phase is 10:1.[241]

In the fused state potassium iodide and sodium iodide are miscible in all proportions and all mixtures are liquid at temperatures above 682°C. Rinck[233] has studied the reaction: $Na + KI \rightleftharpoons NaI + K$ at 800°C., making use of the

technique already described for the sodium–sodium hydroxide reaction (see page 478). Two phases separate, the top layer being an alloy of sodium and potassium, the bottom layer a mixture of sodium and potassium iodides.

Analysis of the metal phase is carried out by determining the total alkalinity, potassium as perchlorate and sodium by difference.

The salt phase is contaminated with the alkali metals dispersed throughout the mass, and a small quantity of the salts is dissolved in water and the solution tested in the following manner: the total alkalinity is determined and on the assumption that the sodium and potassium present are in the same ratio as in the metallic phase, the weight of potassium dissolved in the salts can be calculated. Potassium, determined as perchlorate, is calculated as potassium iodide; the quantity of potassium iodide equivalent to the dissolved metal is subtracted; total iodine is estimated and sodium iodide calculated. The results are given in Table XXVI.

The sodium–sodium halide systems have been studied by Bredig, Johnson and Smith[242] who state that no solid halides such as Na_2X have been found to exist.

The equilibrium between sodium, calcium and their chlorides in the fused state has been studied by Lorentz and Winzer.

Pure sodium and anhydrous calcium chloride ($CaCl_2$, 99·30%; CaO, 0·05%; SiO_2, 0·12% with a trace of aluminium) were heated with sodium chloride in a sealed tube and the equilibrium state was fixed by chilling the melt and breaking the tube under ether. The metal, which readily separates from the

$[Na][KI]/[K][NaI] = 56$ at 800°C.

salt phase, was treated first with methanol to remove sodium and then with water, the calcium being finally precipitated as oxalate and weighed as calcium sulphate.

The results are given in Table XXVII which also includes the solubilities of the metals in the melts. The latter have been found by treating the salt phase with water and titrating the alkali formed with 0·1N-HCl using methyl orange as indicator. The solubilities of calcium plus sodium are expressed as g. of sodium per 100g. of melt. There is a miscibility gap in the curve, cf. Fig. 8, in the region 16–98·5% calcium chloride; no variations other than those due to analytical errors can be detected for a temperature interval of over 300°.[243,244]

The system has been examined in the presence of lead or antimony by the same authors.[245]

Very pure lead and bright metallic sodium are melted together in a stream of dry, oxygen-free nitrogen in graphite crucibles and the sodium–lead alloy cast in bars by pouring into 'Supremax' tubes heated at 500°C.

Calcium chloride and the alloy are heated together in glass tubes which are drawn to a capillary but are sealed only after heating to the required reaction temperature. After chilling to preserve the equilibrium state the salt and metal phases are analyzed.

In Table XXVIII, atom-%Na or Ca in columns 2 and 3 refers to the ratio Na/Na + Ca or Ca/Na + Ca, no regard being paid to the lead used as a diluent.

The equilibrium, $Ca + 2NaCl \rightleftharpoons CaCl_2 + 2Na$ is displaced to the right

when lead is added to the metal phase and the displacement increases until the ratio Pb/(Na + Ca) is about 8; the addition of more lead produces no further change.

The results obtained by adding antimony to the metal phase are given in Table XXIX.

The equilibrium is displaced by the addition of antimony in the same way as with lead but the magnitude of the displacement is different.

Since sodium and calcium chloride are more readily attacked by air than are calcium and sodium chloride, Rinck,[233,246] in investigating the reaction

between sodium and calcium and their chlorides in the fused state, preferred to start with calcium and sodium chloride. The calcium metal was fractionally distilled under reduced pressure and freed from nitride and oxide; calcium chloride was dehydrated by heating at 850°C. in hydrogen chloride, sodium chloride by fusing in a platinum crucible; pure commercial sodium was used without further purification. The reactants were heated in a steel tube provided with a welded lid.

After being chilled, the metallic phase was treated first with alcohol and then with warm water, and the milky liquid analyzed for total alkalinity and calcium.

The salt phase contains small amounts of sodium and calcium which are determined.

Rinck's results, which are different from those of Lorentz and Winzer, are given in detail in Table XXX.

In Fig. 9 the concentration of calcium chloride in the salt phase is plotted against total concentration of calcium in the metal phase, and the isotherms represent equilibria where a change in the composition of the salt phase produces a change in that of the metal phase. At the points *a*, *b*, *c*, *d* a new metallic phase appears, *i.e.* a saturated solution of sodium in calcium; as long as the two metallic phases co-exist, the concentration of the salt phase remains constant. If calcium is added to the system the respective points are

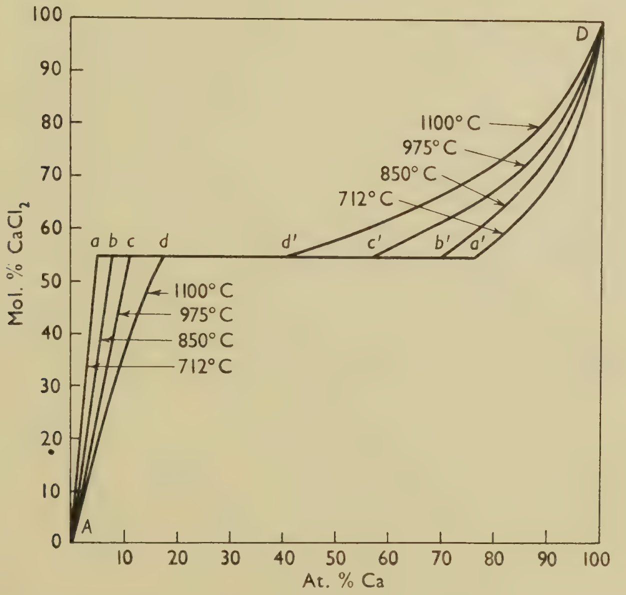

FIG. 9. ISOTHERMS OF THE REACTION: $2NaCl + Ca \rightleftharpoons CaCl_2 + 2Na$

displaced towards a^1, b^1, c^1, d^1 on a line parallel to the abscissae, and at a_1, b_1, c_1, d_1 the light metal phase disappears. The composition of the metal phase at the points of change in variance indicates the solubility of one metal in the other at the temperature of the isotherm.

As long as the molecular ratio of Ca/NaCl is not greater than 0·44, the metallic phase is a solution of calcium in sodium; the solubility of calcium increases with increase in temperature whereas the concentration of calcium chloride in the salt phase decreases. A rise in temperature thus favours the formation of calcium and sodium chloride: $2Na + CaCl_2 \rightarrow 2NaCl + Ca$ and the reaction takes place with evolution of heat. At high temperatures calcium dissolves in sodium with absorption of heat and sodium dissolves in calcium with evolution of heat. A mixture of sodium and calcium chlorides rich in the latter dissolves calcium chloride with absorption of heat whereas a mixture poor in calcium chloride gives out heat when calcium chloride is dissolved in it. The composition of this system at various temperatures is given in Table XXXI.

The solidification diagram for calcium-sodium alloys has been prepared by Rinck.[233]

Equilibria of the type: $2Na + MCl_2 \rightleftharpoons 2NaCl + M$, where M is calcium, strontium or barium, have been studied by Jellinek and Czerwinski.[237,247] An electrolytic method has been used, molten lead serving as the cathode and a carbon rod as anode. Salt mixtures of definite composition were fused above the lead and the operation temperature was about 1000°C. The equilibria conform to the law of mass action and the temperature coefficients of the equilibria studied are exceptionally small. Whereas in aqueous solution at room temperature the sequence of the normal potential of the metals is: lithium, potassium, barium, strontium, sodium, calcium and the difference over the range from lithium to calcium is 0·5V., the sequence at 1200°C. in fused chlorides is potassium, sodium, lithium, barium, strontium and calcium and the difference between the potentials of potassium and calcium at 300°C. is only 0·04V. In Fig. 10 equilibria in the systems $2Na + MCl_2 \rightleftharpoons 2NaCl + M$ and $Na + MCl \rightleftharpoons NaCl + M$ at about 1000°C. are illustrated by plotting at.-% of M in sodium (no account being taken of the lead present) against mol.-% of MCl_2 or MCl in sodium chloride in the original salt mixture.

The theory of equilibrium between metals and salts in fused melts has been discussed by Lorentz.[248] The equations deduced are essentially modifications of the mass action law for condensed systems and the constants calculated for various equilibrium conditions, which include the work of Jellinek and Czerwinski on equilibria of the type $2Na + MCl_2 \rightleftharpoons 2NaCl + M$ where M is calcium, strontium or barium, agree fairly well with experimental values.

Sodium reacts with calcium chloride in an atmosphere of hydrogen according to the equations: (*a*) $2Na + H_2 \rightarrow 2NaH$; (*b*) $2NaH + CaCl_2 \rightarrow CaH_2 + 2NaCl$. The temperature for reaction (*b*) must be above the dissociation temperature of sodium hydride but below the fusion temperature of the charge.[249]

Metallic calcium and/or calcium hydride are obtained by reduction of anhydrous calcium chloride with sodium in the presence of hydrogen.[250]

The equilibrium between sodium and aluminium and their chlorides or fluorides in the fused state closely follows the ideal mass action law. In the system, $3NaCl + Al \rightleftharpoons 3Na + AlCl_3$, the equilibrium between 800° and 900°C. is strongly displaced towards the left and only 0·002 to 0·005% sodium is found in the metal phase and only 0·003 to 0·02% aluminium in the salt phase. The equilibrium constant for $[Na]^3[Al^{+++}]$ is $5{\cdot}2 \times 10^{-10}$ at 825°C. and 5·8 ×

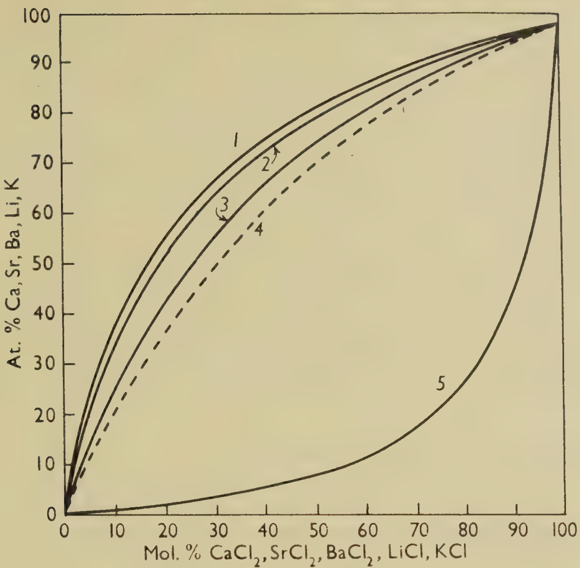

FIG. 10. EQUILIBRIA: $2Na + MCl_2 \rightleftharpoons 2NaCl + M$

10^{-10} at 900°C. In the reaction, $3NaF + Al \rightleftharpoons 3Na + AlF_3$, the equilibrium is displaced a little more to the right at 1090°C. than in the chloride system, probably because aluminium is more strongly bound in the complex $[AlF_6]'''$ than in $[AlCl_4]'$. The amount of sodium in the metal phase is 0·004%, 0·01% and 0·1% when the amount of aluminium in the fluoride slag is >12·8%, <12·8% and 1% respectively. From the equilibrium constants above and below 12·8% Al, the dissociation of the $(AlF_6)'''$ complex can be determined. In a pure cryolite melt at 1090°C. the dissociation of the complex $(AlF_6)'''$ is 1–2%.[251]

Above 1090°C. the reaction $AlF_3 + 3Na \rightleftharpoons 3NaF + Al$ proceeds from right to left and sodium is produced. Under reduced pressure sodium can be obtained at a lower temperature. This reverse reaction is used to improve 12% eutectic aluminium alloys in which sodium, liberated from sodium fluoride, refines the silicon grains.[227]

The equilibrium $Na + KCN \rightleftharpoons K + NaCN$ has been investigated by Lemke.[252] The apparatus is such that a central partition in the container divides it into two compartments of which one (*A*) contains fused potassium chloride and the other (*B*) fused sodium cyanide. Molten sodium is added and floats on the surface of the salts and the addition of sodium is continued until the layer of sodium rises to a level above the central partition to form a 'bridge' between the two fused salts. At (*A*) potassium is extracted from potassium chloride and is replaced by an equivalent amount of sodium. The potassium rapidly diffuses through the metal layer to the cyanide side where it displaces an equivalent amount of sodium from sodium cyanide to form potassium cyanide. The process continues until chemical equilibrium is reached. The resulting potassium cyanide–sodium cyanide may be caused to react with a fresh batch of potassium chloride in a second stage of the process and similarly the chloride melt may react with fresh sodium cyanide. By varying the number of stages the composition of the cyanide and chloride melts can be controlled, or the control may be effected by varying the ratio of potassium chloride to sodium cyanide fed to the apparatus. This technique can be used in other applications provided that the salts melt at a temperature below the b.p. of the alkali metals and that the anions are not reduced by alkali metals. Thus the above double countercurrent extraction may be applied to the exchange of alkali metals between hydroxides, bromides, iodides, chlorides and cyanides.

Experimental values for the equilibrium constant [Na][KCN]/[K][NaCN] = 8·7 at 680° where the quantities in brackets represent mole-% of the respective salts in the salt phase and of the respective metals in the metal phase. From this result and the equilibrium constants given by Rinck for the reactions $KCl + Na \rightleftharpoons K + NaCl$ and $KOH + Na \rightleftharpoons K + NaOH$ the equilibrium constants for the reactions $NaCN + KCl \rightleftharpoons KCN + NaCl$ and $NaCN + KOH \rightleftharpoons KCN + NaOH$ have been calculated.

The reduction of titanium tetrachloride to titanium by the sodium process is now carried out on a commercial scale, and metallic titanium, which withstands severe corrosive conditions and is resistant to seawater attack, is now available as also are its alloys, which have the strength of high tensile alloy steel with only half its weight and withstand high temperatures better than other light metal alloys.

The literature contains many references to this reaction particularly in patents, and these are here briefly outlined.

Most of the processes described, some of which are continuous,[253-309] refer to the reduction by sodium metal of the tetrachloride but the other halides, excepting the fluoride, may also be used. In one example excess of titanium tetrachloride is reduced with sodium and the products, titanium, sodium chloride and excess titanium tetrachloride are leached with water containing an oxidant, such as nitric acid, to retard adsorption of hydrogen on the washed titanium product.[253] Reduction of the tetrachloride, bromide or iodide may be effected by metallic sodium in the presence of zinc or cadmium; free titanium is obtained by distilling off the alloying metal from the molten titanium-zinc or titanium–cadmium alloy.[262] Reduction may be carried out in the liquid or vapour phase using atomized liquid sodium in an inert atmosphere; ductile titanium is produced.[263] A review of the literature up to 1955 is given by Kroll[310] and an account of the early history of titanium and its production by the sodium process by Hunter.[311]

The molar free energy, ΔG(g.-cal.) for the reaction: $TiCl_4 + 4Na \rightleftharpoons Ti + 4NaCl$ is $-226,200 + 65{\cdot}2T$.[312] A review of the thermodynamics of the reaction is given by Sergeev.[313] Equilibria in fused salts containing titanium tetrachloride and alkali metal have been studied by Resnick and Hornstein[314] and the conditions necessary for the formation of titanium investigated.

Titanium tetrachloride has also been reduced to titanium by sodium-potassium alloy,[315] by high surface sodium adsorbed on an inert carrier such as sodium chloride[64] and by sodium amalgam.[316-324]

Titanium or zirconium tetrachlorides are reduced by a continuous method to the subhalides by heating with 1–3 equivalents of sodium at a temperature between the fusion point of sodium and that of the sodium chloride.[309]

The additive compounds obtained when the chlorides of titanium, nickel, chromium, boron, aluminium, silicon, vanadium, manganese and beryllium are treated with ammonia or organic bases are reduced with sodium amalgam to the metal. The amalgam may be obtained in the reduction process by adding for example mercury during the electrolysis of a molten mixture of alkali halide and aluminium chloride. The amalgam formed reacts with the residual aluminium chloride to give aluminium.[327]

Titanium tetrachloride is reduced by sodium in liquid ammonia solution to metallic titanium, identified by electron diffraction; complex titanium salts containing nitrogen are also formed: TiNCl, NaNTiNH and $Na[Ti(NH)_2]$. Titanium cannot be separated from these complexes by ordinary methods. The existence of a sodium complex has also been noted in the product formed by electrolyzing a solution of sodium chloride in liquid ammonia while adding titanium tetrachloride.[326]

The refractory metals zirconium, hafnium, thorium, vanadium, niobium, tantalum, chromium, molybdenum, tungsten and uranium are produced in a pure crystalline form by the reduction of a halide, preferably a chloride, with sodium amalgam. The metals are not appreciably soluble in mercury nor do they form stable compounds with mercury; up to 1000° C. they are not appreciably soluble in sodium chloride produced in the reaction.[320] Other information concerning the reduction of zirconium halide by sodium amalgam has been recorded.[324]

Ruthenium trichloride when titrated with sodium amalgam in dilute acid solution is reduced and the following colour changes observed: red-brown to sepia-brown and then to the blue of the monovalent ruthenium ion, Ru^+. In strong acid solution the production of a green colour marks the end-point of the titration of Ru^{+++} to Ru^{++} and the colour is said to be due to the presence of an addition product with the strong concentration of acid. Further addition of amalgam gives the blue colour of Ru^+. The reduction may be carried further to give ruthenium metal.[325]

Beryllium, chromium and zirconium are formed in a granular state, and uranium and vanadium as metallic powders, when the corresponding pure anhydrous chlorides are reduced with sodium. The yields are: beryllium, 30%; chromium, 57%; uranium from its pentachloride, 94%. Vanadium tetrachloride is somewhat difficult to reduce and large pressures are developed in the bomb, but the trichloride is readily reduced giving a 93% yield of vanadium; only a 63% yield is obtained from the tetrachloride. Zirconium from zirconium chloride is produced in a 76% yield and from potassium zirconium fluoride in a 96–97% yield.[328]

The reduction of beryllium chloride with sodium in an inert gas atmosphere[329] is described also by Kroll[227] who stresses the need for a fully deoxidized bath; an oxidized beryllium chloride bath produces fine metal crystals, more susceptible to attack by water when the reaction product is leached, especially in the presence of chloride ions. Beryllium chloride dissolved in sodium chloride, to reduce evaporation losses of the former, reacts with sodium in the presence of aluminium, preferably in an inert atmosphere, to form alloys of aluminium with up to 10% beryllium.[227]

A stable complex, beryllium fluoride-sodium fluoride, is formed by the action of sodium on beryllium fluoride. Only a part of the beryllium in the fluoride is obtained as metal: $2BeF_2 + 2Na \rightleftharpoons BeF_2,2NaF + Be$.[227]

Improved processes and apparatus are described for the preparation of zirconium by the reduction of its halides (except the fluoride) with molten sodium at 750°-1000° C. in an inert molten halide bath.[254]

Part of the magnesium used for the reduction of zirconium tetrachloride can be replaced by sodium. Cast iron is better as a constructional material than mild steel when used in contact with hot zirconium; a layer of zirconium carbide is formed by diffusion of zirconium and decreases contamination of the product with iron. Gaseous zirconium tetrachloride is piped to the crucible and the reaction salts repeatedly tapped to make room for more reducing metal.[330]

Zirconium, hafnium, niobium, molybdenum, tantalum and tungsten chlorides are converted to the metal by heating with sodium in a closed reactor at 750° to 1450° C. The reactor is cooled externally so that the walls are below the melting point of the halide of the reducing metal. Sodium is charged and sodium chloride removed continuously to maintain a constant level of molten salt in the reactor. The metals, zirconium and hafnium are withdrawn in the form of a solidified sponge.[260,261]

The separation of tantalum and niobium from their ores involves reduction by sodium of the tantalum and niobium double fluorides formed in one stage of the process.[331] The reduction of a fluoroniobate with sodium to produce niobium is described by Kalchin and Sumarovka.[332]

Zirconium tetrachloride in the liquid or vapour phase is allowed to react with atomized liquid sodium in an inert gas and the rate of addition of the reactants is such that sodium is present in excess of the stoicheiometric proportion.[263] Other processes for reducing the volatile halides of zirconium and hafnium with sodium have been described.[260,261,333]

One of the drawbacks involved in the substitution of magnesium for clean oxide-free sodium for the reduction of zirconium tetrachloride to zirconium is that leaching of the sponge is risky on account of the explosion hazard when more or less finely divided zirconium is brought into contact with water. This is confirmed by recent accidents. Vacuum distillation at an elevated temperature to separate the sodium chloride from the sponge introduces a fire hazard because of thin crusts of pyrophoric sodium, condensed in the cooler parts of the retort, and of the pyrophoric properties of zirconium itself.[227] Accounts of the production of zirconium by reduction of the tetrachloride with sodium are given by Miller[303] by Lustman and Kerze[334] and by Hohn *et al.*[290] In the reduction of zirconium tetrachloride with sodium an important step in the process is the removal of oxide formed by the hydrolysis of the chloride on exposure to moisture. This is effected by resubliming the chloride shortly before the reduction stage. The reduction of an alkali fluozirconate with sodium to produce zirconium powder is carried out as follows. An aqueous solution of zirconyl chloride is converted to tetrafluoride by treatment with hydrogen fluoride, an appropriate amount of potassium fluoride is added and the solution evaporated until the compound K_2ZrF_6 crystallizes. The salt is filtered off, dried and mixed with 10% excess of sodium and loaded into a bomb which is heated to 1000°–1200° C. Excess sodium is disposed of by treatment with alcohol, the zirconium metal powder is leached with water and sodium hydroxide solution, and then with hydrochloric acid, and finally washed with water and dried.

The corrosion resistance of zirconium to sodium is sensitive to the oxide content of the zirconium.

Zirconium metal has also been produced by first reducing the tetra- or trihalide to the divalent halide by liquid sodium amalgam; the halide is then decomposed and hydrogenated. The metal is obtained from the hydride.[319]

Zirconium chloride is reduced smoothly, rapidly and at relatively low temperatures with high-surface sodium adsorbed on a solid inert carrier. The metal produced is of colloidal dimensions, extremely reactive, pyrophoric when exposed to air, and should be used as formed in a continuous or semi-continuous process.[64]

For the reduction of chromium chloride, solid particles are introduced beneath the surface of a liquid pool of a 0·9% sodium amalgam. The amalgam is maintained at 200° C. in an atmosphere of helium and is vigorously agitated. The reaction mass is removed from the surface of the liquid amalgam and heated to volatilize the mercury. The remaining mixture contains metallic chromium in an amount approximately 90% of the chromium content of the chromium chloride originally present.[320]

Cuprous and nickel chlorides are reduced readily by high surface sodium adsorbed on the inert solid carrier, sodium chloride; yields of 80–90% of copper and nickel are obtained at reduction temperatures of 275° C. and 200° to 250° C. respectively.[64]

The halides of iron, copper, zinc, silver, chromium, cobalt, cadmium, tin, manganese, nickel and molybdenum are reduced to pyrophoric metal powders when treated with sodium dispersed in toluene or ether. The optimum reaction temperature for iron chloride is 30° C. and for copper, zinc and chromium chlorides, 85° C. Excess sodium in the reaction mixture is removed by extraction with *iso*propyl alcohol and the metal powders are dried in an inert gas such as nitrogen. Alloy metal powders are made in a similar manner from the appropriate halide salt mixtures.[335,336]

Metal halides are reduced to metal powders by the highly coloured addition compounds formed when sodium metal is added to polynuclear hydrocarbons in 'active ether' media such as 1:2-dimethoxyethane and dimethyl ether. Sodium reacts with naphthalene in 1:2-dimethoxyethane to form a dark green solution which contains the sodium addition compound of naphthalene of empirical formula $C_{10}H_8Na_2$. If nickel chloride is added to this solution, finely divided nickel powder is obtained of an average particle size of less than 20 microns. Iron, cobalt and other metal powders may be obtained in the same way.[337] Ferrous chloride, obtained by almost completely dehydrating ferrous sulphate heptahydrate from nickel waste liquors and treating with hydrogen chloride at 10°-65° C., is converted into high-purity iron by allowing a saturated solution of the chloride to react with sodium amalgams. The last traces of mercury are removed by heating. A completely closed mercury, sodium and chloride cycle is maintained in the continuous process.[338]

Atomic reactions of sodium with volatile polyhalides have been investigated by Heller and Polanyi by the diffusion flame method. In the reaction between sodium vapour and titanium tetrachloride, the partial pressure of sodium is about 3×10^{-3}mm.Hg, that of the inert carrier gas 1–10mm. and the temperature of the reaction about 270° C. Reaction occurs with a noticeable amount of inertia and is sometimes accompanied by a faint bluish glow. The reaction velocity constant k is based on the relation:

$$k = \frac{(\ln p_{Na}/p_0 - \ln R/r)^2}{(R-r)^2} \cdot \frac{\delta}{p_{(halide)}} \cdot \frac{1}{T}$$

where p_{Na}, p_0 are the partial pressures of sodium at the centre and edge of the flame respectively, p_0 being 10^{-5}mm., R and r the radius of the flame and nozzle respectively (r = 0·25cm.), δ the diffusion constant of sodium vapour in the carrier gas, $p_{(halide)}$ the partial pressure of the halide gas in the reaction chamber and T the absolute temperature. The reaction velocity constant is 993 c.c.mole^{-1}sec.$^{-1}$ $\times 10^{-11}$ and the collision number 6·4.[158] The calculated heat of activation is 1 kg.-cal.[115]

The reaction with germanium tetrachloride is practically instantaneous and is accompanied by a blue luminescence which is brought about by reaction (*b*): (*a*) $Na + GeCl_4 \rightarrow NaCl + GeCl_3$; (*b*) $GeCl_3 + GeCl_3 \rightarrow GeCl_4 + GeCl_2 + h\nu$. The reaction velocity constant is 4890c.c.mole^{-1}sec.$^{-1}$ $\times 10^{-11}$ and the collision number 1·3.

The reaction with mercuric chloride has been studied by the highly dilute flame method described previously (see page 450).[92,95-97,105,106,339-343] The reactions which occur are: $Na + HgCl_2 \rightarrow NaCl + HgCl + 25$ kg.-cal.; $Na + HgCl \rightarrow NaCl^* + Hg + 65{\cdot}3$ kg.-cal. (secondary reaction); $NaCl^* + Na \rightarrow NaCl + Na^*$: $Na^* \rightarrow Na + h\nu$. The luminescence is associated with the secondary reaction but is weaker than that produced with the halogens and sodium vapour. The calculated heat of activation is zero.[115]

Similar reactions occur with sodium vapour and mercuric bromide and iodide.[94,343] The primary reaction with mercuric bromide is: $Na + HgBr_2 \rightarrow NaBr + HgBr$; the secondary reaction: $Na + HgBr \rightarrow NaBr + Hg$. The total heat evolved is 86 kg.-cal.

The reaction between sodium vapour and cupric chloride or cupric bromide vapour has been studied by the method of highly dilute flames at 300°C. An intense surface light and a feeble space light are observed, the spectrum of the space light showing little else than the *D* line of sodium. The colour of the surface light for the reaction $CuCl_2$ + Na is bluish-green whereas that for $CuBr_2$ + Na is blue or bluish-violet. The spectrum for the first reaction is almost completely in the region of the cuprous chloride spectrum and that for the second reaction in the cuprous bromide region. The reactions: $CuCl_2 + Na \rightarrow NaCl + CuCl$ and $CuBr_2 + Na \rightarrow NaCl + CuBr$ are believed to be wall reactions giving solid sodium chloride and gaseous cuprous halide.[339]

The light- and precipitation-curves for the reactions between sodium vapour and the halides of cadmium and zinc chloride, carried out by the highly dilute flame method, are of the same type as for the mercury halides. Every collision results in reaction: $Na + CdCl_2 \rightarrow NaCl + CdCl$ (primary reaction); $Na + CdCl \rightarrow NaCl + Cd$ (secondary reaction). The light yields for the flame at the nozzle are much smaller than for mercuric chloride, 11%, and decrease in the order: cadmium chloride, 1·5%, bromide, 1%, iodide, 0·8%, zinc chloride, about 0·2%. Raising the temperature of the reaction zone does not affect the light emission.[343,344]

Sodium vapour at 0·01mm. pressure has been brought into contact with the vapours of tin tetrachloride, tetrabromide and tetraiodide. With an excess of the halide, reduction to the dihalide occurs and there is no deposit of tin on the walls of the vessel. The chloride gives a blue light, the bromide a green one and the iodide a yellow colour. The luminescence is intense and continuous.[345] Heller and Polanyi have studied the reaction of tin tetrachloride with sodium vapour by the highly dilute flame method and found it to be practically instantaneous and accompanied by a blue luminescence. The primary reaction is: $Na + SnCl_4 \rightarrow NaCl + SnCl_3$; the secondary reaction: $SnCl_3 + SnCl_3 \rightarrow SnCl_4 + SnCl_2 + h\nu$ which brings about the luminescence. The reaction velocity constant obtained when sodium vapour at a pressure of about 3×10^{-3}mm.Hg is allowed to react with the vapour of tin tetrachloride in an inert gas atmosphere at 1–10mm. pressure at 270° C. is $3510 c.c.mol.^{-1} sec.^{-1} \times 10^{-11}$ and the collision number 1·8.[158,346] The heat of activation for the above reaction is zero.[115]

Violent reaction occurs when sodium is heated with vanadium oxychloride, $VOCl_3$, at 180° C.[347]

Mixtures of sodium with certain halides explode when subjected to mechanical shock as indicated in Table XXXII.[112]

No reaction occurs between sodium and the following halides when mixtures are subjected to shock: sodium, magnesium, calcium, strontium, barium halides; silver chloride, bromide, iodide, zinc fluoride and bromide, manganese fluoride and iodide and the complex, $UCl_4,2KCl$.

Anhydrous sodium fluotitanate, added to molten sodium in the ratio of four equivalents of sodium to one mole of the fluotitanate, is reduced to titanium by heating in an inert atmosphere at 500° to 1300° C.[348]

There is no appreciable reaction between sodium and sodium tungstate, Na_2WO_4, at 900° C. When mixtures of sodium with sodium tungstates, formed by heating the compound, Na_2WO_4 with different proportions of tungsten oxide, WO_3, were heated at 900° C., the yield of tungsten was in the following order according to the proportion of oxide used: $5NaO_2,12WO_3 > Na_2W_2O_7 > Na_2WO_4$. It is concluded that the reactions are: $WO_3 + 6Na \rightarrow 3Na_2O + W$ and $3Na_2O + 3WO_3 \rightarrow 3Na_2WO_4$, *i.e.* $4WO_3 + 6Na \rightarrow 3Na_2WO_4 + W$; the reaction is irreversible.[349] Sodium diffusion in sodium tungsten bronzes has been measured in single crystals of the substance $Na_{0.78}WO_3$ at 664°, 752° and 832° C. The data obtained from several crystals held at constant temperature for varying periods give a family of curves showing the sodium concentration as a function of depth and time. From these curves the mass of sodium transferred through a plane parallel to the surface and at any particular depth can be obtained. The slope of this curve divided by the concentration gradient, both evaluated at the same time and depth, is taken as the diffusivity for the corresponding concentration.

TABLE XXXII. - EFFECT OF SHOCK ON MIXTURES OF SODIUM AND HALIDES

Halide	Type of explosion	Halide	Type of explosion	Halide	Type of explosion
CCl_4	Very violent	IBr	Strong	SBr_2	Strong
PCl_5	Very violent	BBr_3	Strong	$CrCl_4$	Strong

The diffusivity of sodium in $Na_{0.78}WO_3$ is represented by the equation $D = D_0 \exp(-\Delta H/RT)$ where $D_0 = 0{\cdot}87$ sq. cm./sec. and $\Delta H = 51{\cdot}8$ kg.-cal./mole. For $Na_{0.8}WO_3$ the length L at temperature T_c is given by $L = L_0[1 + (8{\cdot}81 \times 10^{-6})T_c - (1{\cdot}92 \times 10^{-9})T_c^{\,2}]$, where L_0 is the length at 0°C.[350] The electrical properties of the sodium tungsten bronzes have been tabulated by Juretschke.[351]

Silicon tetrachloride is reduced to silicon, smoothly, rapidly and at relatively low temperatures, 160° to 220°C., by sodium dispersed on sodium chloride as an inert carrier.[64]

Reduction of silicon tetrachloride with sodium yields silicon containing 2 p.p.m. of boron.[269] For producing high purity silicon this process is more economical than hydrogen reduction or reduction of silicon monoxide.[352] Lower halides and mixed halides of Group IVb, Vb and VIb elements and silicon are obtained by gas phase reduction of higher halides with insufficient sodium for complete reduction. They may be further reduced if required.[353] When monochlorosilane, SiH_3Cl, is shaken for 16hr. with sodium amalgam (1g. of sodium in 10c.c. of mercury) a mixture of hydrogen and silane, SiH_4, but no silicoethane, Si_2H_6, is obtained. The reaction is considered to be: $2SiH_3Cl + 2Na \rightarrow Si_2H_6 + 2NaCl$, the silicoethane decomposing with sodium as it is formed to give hydrogen and silane. Silicoethane in the nascent state reacts more rapidly with sodium than in the molecular form. Dichlorosilane reacts with sodium amalgam to give hydrogen and silane; no unchanged dichlorosilane remains.[354]

Atomic reactions of sodium with the halides of boron and silicon and the oxychloride of chromium have been studied by the diffusion flame method at low pressures and in the presence of an inert carrier gas at 270°C. The partial pressure of sodium vapour is about 3×10^{-3}mm. and that of the carrier gas 1-10 mm. Boron trichloride and silicon tetrachloride show the greatest inertia. No luminescence is observed in the reaction with silicon tetrachloride; with silicon tetrabromide a yellow luminescence occurs, with boron trichloride a grey luminescence, with boron tribromide a blue luminescence and with chromium oxychloride a much more intense light of a blue-green colour accompanies the reaction. With all but silicon tetrachloride, a continuous spectrum is observed. Table XXXIII gives the reaction velocity constants and the collision numbers.[158]

TABLE XXXIII. - ATOMIC REACTIONS OF SODIUM WITH THE HALIDES OF BORON AND SILICON AND THE OXYCHLORIDE OF CHROMIUM

Halide	Reaction velocity constant (k) c.c.mole^{-1}sec.$^{-1}$ × 10^{-11}	Collision no.
$SiCl_4$	4·03	1570·0
$SiBr_4$	1450·0	4·4
BCl_3	4·71	1350·0
BBr_3	248·0	25·6
CrO_2Cl_2	1330·0	4·8

Boron trifluoride is reduced to boron by reduction with sodium. Sodium vapour, diluted with helium, is passed into a reactor into which boron trifluoride is introduced separately. The mixture is heated to start the reaction which is then self-maintained at about 1500° C. Crystalline boron is obtained. The most suitable material for the reactor is boron carbide, B_4C, which withstands the high temperature and is inert to boron. Liquid sodium may be sprayed into the reactor instead of using sodium vapour.[355]

Sodium and hydrogen react with boron trifluoride: $4Na + 2H_2 + BF_3 \rightarrow NaBH_4 + 3NaF$; $6Na + 3H_2 + 2BF_3 \rightarrow B_2H_6 + 6NaF$. The molten alkali metal is atomized into a current of dry hydrogen supplied under pressure and heated to avoid chilling the metal and to accelerate the reaction. Sodium hydride is formed with liberation of heat and reacts with the boron-containing compound. The reaction temperature is adjusted to 150°-350° C. The reaction products are passed into a closed collecting chamber; the solid products settle to the bottom while the gaseous products such as boranes and excess hydrogen are withdrawn for appropriate recovery. Other reactions which may be brought about in this way are: $12Na + 6H_2 + 3BF_3 + AlCl_3 \rightarrow Al(BH_4)_3 + 12NaF$; $9Na + 3BF_3 + 3NH_3 \xrightarrow{H_2} B_3N_3H_6 + 9NaF + 1{\cdot}5H_2$. The metallic borohydrides are excellent reducing agents and provide efficient sources of hydrogen.[356]

Boron trichloride is reduced to crystalline boron by the action of dispersed sodium.[355] The heat of fomation, ΔH, and free energy, ΔF° for the reaction: $3Na(c) + BCl_3(g) \rightarrow 3NaCl(c) + B(c)$ are −200·2 and −184·45kg.-cal. respectively at 298°K.[33]

Boron chloride, fluoride or bromide reacts with hydrogen at 200°-400°C. in the presence of an alkali metal, an alkali earth metal, magnesium, aluminium or zinc to give boron hydrides. A diluting gas, e.g. argon, helium or nitrogen, may be mixed with the halide and hydrogen. An example is given using granular aluminium, but the aluminium may be replaced by molten sodium. The products are condensed at −190°C. and distilled.[357]

Sodium, hydrogen and methyl borate, $B(OCH_3)_3$, under pressure at 250°C. give mainly the compound $NaBH(OCH_3)_3$ and small amounts of sodium borohydride, $NaBH_4$.[358] Sodium borohydride is, however, produced in almost quantitative yield by agitating molten sodium with a high shear in a refined high boiling mineral oil, heating in a hydrogen atmosphere and adding methyl borate to the finely dispersed sodium hydride. The sodium borohydride is extracted with a solvent and dried. Sodium methoxide is also formed. The sodium dispersion technique has several advantages; the rate of hydride formation is faster and the oily coating makes it easier to handle; the reaction of methyl borate with sodium hydride formed in this way is ten times faster, it does not require excess hydride and proceeds efficiently. The oil absorbs the heats of solution and reaction thus preventing decomposition which might result from over-heating.[65] In the rapid reaction between sodium hydride and methyl borate at 225°–275° C. to produce sodium borohydride (which is extracted in almost quantitative yield with *iso*propylamine) ethyl and butyl borates and $NaB(OCH_3)_3$ and $NaB(OCH_3)_4$ can be substituted for methyl borate.[358]

The reaction: $4Na + 2H_2 + B(OCH_3)_3 \rightarrow NaBH_4 + 3NaOCH_3$ is carried out as described above for the reaction with boron trifluoride.

The action of sodium amalgam on boron hydrides causes condensations and not removal of hydrogen as with silicon hydrides.[359]

Molten aluminium chloride monoammine reacts with sodium to give hydrogen: $AlCl_3NH_3 + 3Na \rightarrow AlCl_3Na_3N + 1{\cdot}5H_2$. The liberation of hydrogen is probably due to the changed inner structure of the NH_3 molecule when present in the molecule $AlCl_3,NH_3$.[360]

In a study of electrolytic conduction processes in glass using electric light bulbs suspended in electrolytes of sodium chloride, sodium bichromate solutions and fused sodium nitrate–sodium nitrite mixtures, the lamp filament being used as the cathode, the sodium of the glass was more or less replaced by the anion of the electrolyte.[361]

The action of sodium on evacuated Pyrex vessels for a prolonged time is only slight at 230° C. but at 350° to 400° C. the glass becomes dark brown in colour and on cooling the sodium appears to crystallize inside the glass. The brown product is slightly soluble in alcohol and readily soluble in water. The weight of glass dissolved by sodium after heating *in vacuo* for 7hr. at 350° C. is about 0·005g. per 14·4g. of glass.[362]

When finely ground Thüringian glass is shaken with a sodium–silver nitrate melt for 4hr. at 380°C., the displacement of sodium by silver in the glass rises rapidly to over 90%, when the melt contains 20mole-% of silver. With pure silver nitrate, all the sodium is replaced by silver. No appreciable amount of sodium is displaced when the glass is treated in a silver bromide bath.[363]

Sodium-resistant glass, suitable for electrical discharge work, contains about $30\%B_2O_3$, not more than $50\%SiO_2$ nor more than 0·1% of iron oxide, with alkalis, alkali earths and aluminium oxide.[364] Other compositions given are: $50–75\%B_2O_3$, $3–15\%SiO_2$ and less than 10% of alkali metal oxide; or 25–30% BaO, $50–20\%B_2O_3$ and less than about $20\%SiO_2$.[365]

A glass resistant to metal vapours such as sodium, and suitable for alkali metal lamps, contains 10–40% of boric acid, 10–35% of alumina, a total of not more than 5% of tetravalent oxides and oxides of antimony, arsenic, lead and alkali metals and 25–80% of bivalent oxides (but not more than 5% of zinc oxide); the sum of 1½times the percentage of bivalent oxides plus the percentage of alumina equals at least 45%.[366]

Other references have been made to rendering glass resistant to attack by sodium vapour.[367-372]

The rate of penetration of the reaction of a molten metal such as sodium into a vitreous or an agglomerated oxide, such as SiO_2, is determined by the temperature and the ratio of $B:A$ where A and B are the molecular volumes of the initial oxide and the reaction product respectively at the temperature of the reaction. When B/A is greater than 1, as in Table XXXIV, the reaction soon stops because of the formation of a protective layer; when B/A is less than 1 the protecting layer contains fissures that permit further attack on the oxide by the molten metal.

TABLE XXXIV. - REACTION OF SODIUM WITH SILICA

Solid phase	Liquid phase	Products		Temp. °C.	A	B	B/A
		Insoluble	Soluble				
SiO_2 (glass)	Na	Na_2O Na_2SiO_3	Si	250	27·2	55·2 34·4	2·03 1·26

The attack of sodium on vitreous silica at 250° C. is superficial.[373]

Sodium can be stored for long periods at room temperature in 2–3mm. glass tubing about 50cm. long. The sodium is melted and driven into the tubes; only the open end is subject to oxidation. The end section is broken off and discarded and short lengths of the tube are added directly to a reactor.[374]

The efficiency of the dealkalization of glass surfaces has been determined by the use of radioactive sodium. Glass specimens have been irradiated with deuterons to change some of the ^{23}Na isotope in the glass to the radioactive isotope ^{24}Na. When heated in contact with a dealkalizing agent (clay or chromium trioxide), some of the radioactive sodium is transferred from the glass to the agent. The agent is scraped from the glass surface after cooling and from the composition and distribution of induced radioactive sodium the efficiency of the agent can be determined.[375] The appearance, chemical constitution, hardness and electrical conductivity of non-metallic materials containing silica, such as glasses and ceramics, can be altered without changing their form or size by heating to 700°–900° C. in contact with reducing metals such as sodium for a sufficient time to transform *in situ* a substantial part of the siliceous material to one with a metallic appearance. Particles of sodium oxide are embedded in a matrix of an alloy of the metal with silicon.[376] In an investigation of the structural effects on colours in glass, Cole[377] suggests that alkali metals can assume a covalency of four in glasses by accepting co-ordinate links from lone pairs of electrons from oxygen in the silicon network. The experimental work on amber coloured glass shows that with constant amounts of colouring additions, iron oxide, sulphur and carbon, the depth of colour is increased when silica is replaced by soda in a base glass composition. The deepening of colour is assumed to occur by a process analogous to reduction and that with the exception of the special effect of zinc oxide, the colour becomes paler by an oxidation effect. The alkali metals arranged in order of increasing reducing power *i.e.* increased basicity are: potassium, sodium, lithium.

Polythene can be used as a casing material for sodium; no reaction occurs and the metal does not adhere to the polythene.[378]

Sodium metal aids the bonding of Teflon. After solvent cleaning, Teflon is dipped into a 1% solution of metallic sodium in liquid anhydrous ammonia for a few seconds, then quenched in water and allowed to stand in air. It can then be cemented to aluminium, mild steel, wood or Teflon with conventional adhesives.[379]

Good resistance to corrosion by sodium liquid or vapour at 900°C. is shown by molybdenum, tungsten, tantalum, synthetic sapphire, single-crystal magnesium oxide, molybdenum silicide, $MOSi_2$, and sintered thoria. Good resistance to corrosion by sodium after 100 hours at 1500° C. is shown by molybdenum wire.[380]

The corrosive resistance of various metals and alloys in sodium is illustrated by bar graphs which indicate approximate temperatures below which static and dynamic systems might be operated for 1000hr. with less than 0·005 in. of attack or container surface removal. For temperatures below 1500°F., the austentitic (300 series) stainless steels are the most satisfactory materials. Oxygen is the most troublesome impurity and should be avoided if mass transfer is to be minimized. Nickel-base alloys such as Inconel (approximately 77%Ni, 15%Cr, 7%Fe) suffer temperature-gradient mass transfer in dynamic sodium systems above 1400°F. The metal crystals deposited in the cold sections contain approximately 90%Ni, 8%Cr and <0·5%Fe, which indicates the preferential transfer of nickel by sodium. The precious metals have very poor resistance to liquid alkali metals even at moderately low temperatures. Carbon is readily transferred between two metals of different carbon content when in contact with sodium, or a monometallic system may be carburized owing to a high carbon concentration in the sodium. The walls of a stainless steel capsule in contact with sodium intentionally contaminated with carbon for 100hr. at 1500°F. were heavily carburized to a depth of 15mils. Contamination of sodium by various hydrocarbons may also result in subsequent carburization of metal containers.[33,381,382] Numerous other authors refer to corrosion by liquid sodium.[383-404]

Problems associated with the use of sodium as a coolant such as corrosion, mass transfer, diffusion bonding, induced activity, preferential attack of certain materials, blockage by oxides and the effects of oxygen on the behaviour of materials have been discussed by Brush and Koenig.[405] A preliminary study has been made of the fatigue of stainless steel in contact with liquid sodium at 300°C.[406]

Sodium reacts with oxygen-containing salts such as nitrates, sulphates, hydroxides, chromates, manganates, silicates but not with sodium carbonate or sodium monoxide. It is inert to molten baths of its halides, amide, cyanide and hydride.[143] Silicates, alkaline earth sulphates and lead sulphate are decomposed by sodium at a dull red heat.[207]

Chemical reactions with alkali metals, such as the removal of water or hydroxylated organic compounds from liquids, are exemplified by the use of molten sodium to remove small amounts of *iso*butyl alcohol from *iso*butyl vinyl ether.[408]

Alkali metal dispersions, which are stable against settling and agglomeration and in which the dispersed metal does not exceed 50μ in size, are prepared in an inert liquid hydrocarbon having a boiling point above the melting point of the metal, and in the presence of an emulsifying agent, such as 1:10-dimethoxy-3:7-decadiene. Under suitable conditions this process is said to give a stable dispersion in which the average size of the sodium particles is 8μ. The unusually finely divided form of the metal may be used as additives for Diesel fuels of inferior ignition characteristics to increase the cetane number of the fuel. Compounds suitable as emulsifying agents are complex addition compounds of the type (*a*) alkali metal alkoxides of the general formula, MOR, where M is an alkali metal and R an aliphatic, *cyclo*aliphatic or aromatic radical or (*b*) alkali metal organic compounds in which an alkali metal atom is directly attached to an allylic residue, *i.e.* compounds with at least one residue of the structure C:CCM where M represents an alkali metal. The addition compounds of either type in which the ratio of total carbon atoms to total alkali metals is 2–7:1 are preferred.[409]

Alkali metal vapours may be separated from gases by absorption in molten tin distributed as discrete drops throughout a mass of granular refractory material, such as a mixture of 120g. of 30-mesh tin and 480g. of 40-mesh silicon carbide.[410]

The handling of sodium, the hazards and precautions necessary in working with sodium are described by a number of workers.[33,91,382,411-413]

Other references to the chemistry and industrial uses of sodium are given.[414-418]

REACTIONS OF SODIUM IN LIQUID AMMONIA

A. Inorganic Reactions in Liquid Ammonia.

The oxidation of sodium in liquid ammonia has been investigated by several workers. Kraus and Whyter passed a controlled stream of oxygen through a solution of the metal at liquid ammonia temperatures and measured the volume of oxygen absorbed and the weights of the products formed. On slow oxidation, sodium hydroxide and sodium amide are formed: $2Na + 0{\cdot}5O_2 \rightarrow Na_2O$; $Na_2O + NH_3 \rightarrow NaOH + NaNH_2$. On further oxidation the amide is oxidized to sodium nitrite: $2NaNH_2 + 1{\cdot}5O_2 \rightarrow NaOH + NaNO_2$. On rapid oxidation sodium peroxide is produced and is stable in liquid ammonia. No evidence of the formation of a higher oxide is obtained, contrary to the observations of Joannis[2] who claimed to have obtained an oxide Na_2O_3. The product, Na_2O,NH_3, found by Joannis, is considered by Kraus and Whyte to be a mixture of sodium hydroxide and amide.

Evidence for the existence of sodium superoxide, NaO_2, in liquid ammonia is given by Schechter, Sisler and Kleinberg.[3] Oxygen is passed at a rate of about 900cm.^{3}/min. through solutions of sodium in liquid ammonia at −77°C. and the volumes of gas absorbed and liberated from the solid residue are given in Table XXXV.

It is highly probable that sodium superoxide is formed at −77°C., the small amount of oxygen liberated from the solid residue being no doubt due to the instability of this oxide. The residue before analysis was obviously heterogeneous and appeared to be a mixture of yellow and white substances. If the reaction is so controlled that the blue colour of a solution of sodium in liquid ammonia is not formed, the product obtained by the rapid oxidation of sodium corresponds to the formula $NaO_{1\cdot67}$ *i.e.*, $Na_2O_2,4NaO_2$. The presence of sodium superoxide is confirmed by magnetic measurements. The uncontrolled reaction produces some sodium nitrite by oxidation of the amide.[4,5]

The solutions of sodium superoxide in liquid ammonia are yellow and some

TABLE XXXV. - ABSORPTION OF OXYGEN BY SODIUM IN LIQUID AMMONIA AT –77° C.

Na g.	Dilution cm.^{3}NH$_3$/g.Na	% Theoretical uptake of O_2	% Theoretical liberation of O_2
0·02	380	90	56
0·0616	680	86	50
0·0183	1200	90	54
0·0293	1830	87	56
0·0191	2490	90	50

yellow matter is suspended in them. After removal of the solid matter, absorption studies show a maximum on the absorption curve at about 380mμ due to the presence of the superoxide which is less soluble than the lithium oxide but more so than potassium superoxide.[6]

Sodium superoxide is soluble to the extent of about 0·3g. in 100cm.^{3} of liquid ammonia and undergoes some decomposition when stirred in this medium.[7]

The action of ozone on solutions of sodium in liquid ammonia at -70° C. probably results in the formation of ozonide but the compound is too unstable to permit isolation and analysis. A gelatinous white mass of the hydroxide is first formed, the blue colour of the metal solution disappears, the hydroxide dissolves and a deep orange solution and a precipitate are formed. The readiness of formation and the stability increase in the order, sodium, potassium, rubidium and caesium. Much nitrate is also formed.[8]

Sulphur reacts very readily with solutions of sodium in liquid ammonia at -33° C. A white, apparently amorphous precipitate of the monosulphide is first formed, followed by further reaction with sulphur to give light yellow or orange disulphides. These in turn are converted into readily soluble tetrasulphides which form orange-yellow solutions. The following reactions occur: $2Na + S \rightarrow Na_2S$; $Na_2S + S \rightarrow Na_2S_2$; $Na_2S_2 + 2S \rightarrow Na_2S_4$; $Na_2S_4 + (x - 4)S \rightarrow Na_2S_x$.[9] Sodium monosulphide, which is white, becomes coloured on exposure to moist air.[10]

The results shown in Table XXXVI have been obtained by potentiometrically titrating a suspension of pure sulphur in liquid ammonia, to which sodium iodide is added to increase the conductivity of the solution, with a liquid ammonia solution of sodium.

TABLE XXXVI. - POTENTIOMETRIC TITRATION OF SULPHUR IN LIQUID AMMONIA WITH A LIQUID AMMONIA SOLUTION OF SODIUM

Temp. °C.	Contents of reaction vessel	In burette	Point of inflexion ml.	Composition of compound
-60	369·1mg.S + 200mg.NaI in 80ml.NH_3	578·0mg.Na in 74·18ml. NH_3	10·34 13·39 16·69 65·79	Na_2S_6 Na_2S_5 Na_2S_4 Na_2S
-61	63·1mg.S + 200 mg.NaI in 70 ml.NH_3	102·7mg.Na in 74·03ml. NH_3	10·88 15·95 22·35 30·68 65·54	Na_2S_6 Na_2S_4 Na_2S_3 Na_2S_2 Na_2S
-60	47·2mg.S + 200mg.NaI in 70ml.NH_3	73·8mg.Na in 75·43ml. NH_3	9·90 11·51 13·83 16·82 68·00	Na_2S_7 Na_2S_6 Na_2S_5 Na_2S_4 Na_2S

Solutions of the sulphur-rich polysulphides are an intense red colour, and as the titration proceeds they become light yellow, finally yielding a white precipitate of sodium monosulphide. It is only at certain concentrations that the compounds Na_2S_7, Na_2S_5 and Na_2S_3 are formed.[11]

The preparation of sodium monosulphide from its elements in liquid ammonia is also described by Klemm, Sodomann and Langmesser.[12]

Potentiometric titrations of liquid ammonia solutions of the alkali polysulphides with liquid ammonia solutions of the alkali metals have been conducted at −38° C. by Watt and Otto. In the case of sodium, salts of the type Na_2S_4 and Na_2S are formed.[13]

Selenium reacts very readily with liquid ammonia solutions of sodium at −33° C. to give initially a white, sparingly soluble and apparently amorphous precipitate of the monoselenide: $2Na + Se \rightarrow Na_2Se$. Further reaction with excess of selenium gives di- and poly-selenides.[9,10,12]

The results given in Table XXXVII are obtained by potentiometric titrations of a suspension of selenium in liquid ammonia, containing sodium iodide to increase the conductivity of the solution, with a solution of sodium in liquid ammonia.[11]

TABLE XXXVII.- POTENTIOMETRIC TITRATIONS OF SELENIUM IN LIQUID AMMONIA WITH A SOLUTION OF SODIUM IN LIQUID AMMONIA

Temp. °C.	In reaction vessel	In burette	Point of inflexion ml.	Composition of compound
−60·0	104·8mg. Se + 200 mg. NaI in 75ml. NH_3	70·8mg. Na in 74·03ml. NH_3	12·48	Na_2Se_5
			16·07	Na_2Se_4

			32·07	Na_2Se_2
			63·89	Na_2Se
−60·0	32·52mg. Se + 200 mg. NaI in 80ml. NH_3	20·12mg. Na in 75·93ml. NH_3	11·56	Na_2Se_6
			–	Na_2Se_5
			18·20	Na_2Se_4
			24·20	Na_2Se_3
			35·80	Na_2Se_2
			72·34	Na_2Se

Tellurium reacts vigorously with a solution of sodium dissolved in liquid ammonia; a white crystalline precipitate of the normal telluride, Na_2Te, is formed and when all the sodium is used up the solution is yellow. With excess of tellurium higher tellurides are formed.[10,12,14,15]

The reaction between sodium and tellurium in liquid ammonia has also been studied by potentiometric titrations of a suspension of tellurium in liquid ammonia, containing sodium iodide to increase the conductivity of the solution, with a sodium solution. Typical results are given in Table XXXVIII.[11]

The heat of formation of the tellurides, Na_2Te and $NaTe$, measured by Kraus and Ridderhof by determining the heat of reaction and of solution in liquid ammonia at −34° C., is 28·1 and 25·4kg.-cal./g.-atom respectively.[16]

Polyarsenides, as well as the normal arsenide Na_3As, are formed when a solution of sodium in liquid ammonia is allowed to react with freshly sublimed arsenic: $3Na + xAs \rightarrow Na_3As_x$.[17]

Potentiometric titrations of elementary arsenic in liquid ammonia with a solution of sodium in the same solvent give no evidence of compound formation. If, however, a solution of sodium in liquid ammonia is titrated with a liquid ammonia solution of arsenic trisulphide, points of inflexion occur indicating the formation of compounds, as shown in Table XXXIX.

The first compound, Na_3As, is formed as a brown precipitate and the solution

TABLE XXXVIII. - POTENTIOMETRIC TITRATIONS OF TELLURIUM WITH SODIUM IN LIQUID AMMONIA

Temp. °C.	In reaction vessel	In burette	Point of inflexion ml.	Composition of compound
-54·5	187·2mg.Te + 200 mg.NaI in 77·98 ml.NH_3	74·9mg.Na in 77·98 ml.NH_3	19·43 23·33 35·04 71·44	Na_2Te_4 Na_2Te_3 Na_2Te_2 Na_2Te
-60·7	235·4mg.Te + 200 mg.NaI in 60ml. NH_3	94·6mg.Na in 79·18 ml.NH_3	22·17 35·08 69·51	Na_2Te_3 Na_2Te_2 Na_2Te

TABLE XXXIX. - POTENTIOMETRIC TITRATIONS OF SODIUM AND ARSENIC TRISULPHIDE IN LIQUID AMMONIA

Temp. °C.	In reaction vessel	In burette	Point of inflexion ml.	Composition of compound
-50·0	61·9mg.Na in 70 ml.NH_3	123·8mg. As_2S_3 in 80·44ml. NH_3	35·48 54·37 59·23 62·49	Na_3As Na_3As_3 Na_3As_5 Na_3As_7

becomes yellow. As higher polyarsenides are produced the colour of the solution becomes a dark, reddish brown. The presence of sodium sulphide formed in the reaction: $(6x + 6)Na + xAs_2S_3 \rightarrow 2Na_3As_x + 3x\,Na_2S$, produces turbidity.[11]

Gaseous arsine passed into a liquid ammonia solution of sodium at -78° C. reacts very rapidly, changing the colour of the sodium solution from blue to green and finally to a brilliant yellow colour. The disappearance of the blue colour indicates the completion of the reaction: $Na + AsH_3 \rightarrow NaAsH_2 + 0{\cdot}5H_2$. The dihydrogen arsenide is appreciably soluble in liquid ammonia; after removing the solvent by evaporation a pale yellow, almost white, solid remains as crystals on the walls of the reaction vessel. The crystals do not contain ammonia of crystallization and the composition is unchanged after 60hr. *in vacuo* at room temperature.[18]

On reaction with antimony, which is insoluble, the deep blue colour of a liquid ammonia solution of sodium diminishes and a dark brown precipitate collects in the bottom of the cell, the solution finally becoming light yellow in colour. This part of the reaction is very rapid, considerable heat is evolved and the reaction is completed in an hour or two. The compound formed is Na_3Sb. A slower reaction then occurs accompanied by the production of a deep red solution and disappearance of the precipitate. A series of compounds is formed and the ratio of antimony to sodium in compounds in equilibrium with free antimony varies as a function of concentration. Two compounds at least are formed, one of which has a ratio of $Sb/Na > 2$ and one < 2. In dilute solutions the compound of low antimony content is present in relatively larger quantities. Electrolysis shows that antimony is present in solution as the anion and that more than one atom of antimony is associated with each negative charge.[19]

A satisfactory end point cannot be obtained when a liquid ammonia solution of sodium is treated with antimony tribromide; the ratio of $Na/Sb = 4{\cdot}8$ found is probably too high.[20]

The following reaction occurs when sparingly soluble red antimony trisulphide in liquid ammonia is potentiometrically titrated with a solution of sodium in the same solvent as shown in Table XL: $xSb_2S_3 + (6x + 6)Na \rightarrow 2Na_3Sb_x + 3x\,Na_2S$. Red antimony trisulphide is more reactive than the black sulphide. The trisulphide is first reduced to antimony but as the reaction is slow some

TABLE XL. - POTENTIOMETRIC TITRATIONS OF ANTIMONY TRISULPHIDE WITH SODIUM IN LIQUID AMMONIA

Temp. °C.	In reaction vessel	In burette	Point of inflexion ml.	Composition of compound
-57·5	109·2mg. Sb_2S_3 in 60ml. NH_3	98·0mg. Na in 80·99ml. NH_3	38·77 49·11 73·08	Sb Na_3Sb_3 Na_3Sb
-53·5	48·53mg. Sb_2S_3 in 60ml. NH_3	41·55mg. Na in 82·13ml. NH_3	41·13 75·73	Sb Na_3Sb

polyantimonide is formed, producing a deep red solution, before all the trisulphide disappears. The compound, Na_3Sb, is present as a greyish brown precipitate.

A higher polyantimonide, Na_3Sb_7, is obtained by extraction of sodium-antimony alloys with liquid ammonia.[11]

Extraction of a sodium-antimony alloy containing 75at.-% antimony with liquid ammonia gives a residue of antimony and a viscous dark reddish brown solution of sodium polyantimonide, Na_3Sb_7, xNH_3. On evaporation of ammonia a greyish black ammine, $Na_3Sb_7NH_3$, is obtained which is very stable at room temperature and loses ammonia only exceedingly slowly on the vacuum pump. Heating at 100° C. causes the ammonia to be given off suddenly, leaving Na_3Sb_7 which decomposes to the antimonide, NaSb, and antimony.[21]

A review of the work of Kraus and co-workers on compounds of the type, Na_2Te_x, Na_3Sb_x, and photographic plates showing the colours of liquid ammonia solutions of sodium, sodium tellurides, Na_2Te_2, Na_2Te_4 are given by Johnson and Fernelius.[22]

Bismuth reacts with sodium in liquid ammonia to give three compounds: Na_3Bi, which is black and insoluble; Na_3Bi_3, which forms a violet solution; and Na_3Bi_{5-7} which gives a brown solution.[23]

A satisfactory end point cannot be reached when a liquid ammonia solution of sodium is treated with bismuth trichloride. The ratio of Na/Bi = 3·3 in the compound isolated is probably too high.[20]

Bismuth tri-iodide reacts in liquid ammonia with sodium to give the following compounds, Na_3Bi, Na_3Bi_3 and Na_3Bi_5.[24]

The reaction: $(3x + 3)Na + xBI_3 \rightarrow Na_3Bi_x + 3x\, NaI$ occurs when a liquid ammonia solution of sodium is titrated potentiometrically with a liquid ammonia solution of bismuth iodide as shown in Table XLI.

TABLE XLI. - POTENTIOMETRIC TITRATIONS OF SODIUM AND BISMUTH IODIDE IN LIQUID AMMONIA

Temp. °C.	In reaction vessel	In burette	Point of inflexion ml.	Composition of compound
-60	22·44mg. Na in 60 ml. NH_3	207·8mg. BiI_3 in 75·97ml. NH_3	34·12 50·58 56·29 67·68	Na_3Bi Na_3Bi_3 Na_3Bi_5 Bi
-60	45·16mg. Na in 55 ml. NH_3	424·6mg. BiI_3 in 78·08ml. NH_3	34·99 51·88 69·27	Na_3Bi Na_3Bi_3 Bi

The formation of the compound, Na_3Bi_5, is dependent on the concentrations of the solutions.[11]

Sodium bismuth alloys containing 75at.-% of bismuth react very slowly with liquid ammonia and give only weakly coloured yellowish brown solutions. In order to obtain appreciable amounts of reaction products, the extraction must be prolonged for several months. The residue on removal of ammonia from the solution has a composition of $Na_3Bi_{5.85}$ and is considered to be a mixture of Na_3Bi_5 and Na_3Bi_7. These compounds are unstable in the solid state, decomposing to NaBi + Bi.[21]

Bismuth oxyiodide is reduced by sodium in liquid ammonia according to the equation: $BiOI + 3Na + NH_3 \rightarrow Bi + NaI + NaOH + NaNH_2$. With an excess of sodium, bismuthides are formed.[25]

A flocculent black precipitate is formed when a solution of sodium in liquid ammonia is titrated potentiometrically with a solution of thallium iodide in the same solvent; the decolorization of the supernatant liquid coincides with the first inflexion point referred to in Table XLII.

TABLE XLII. - POTENTIOMETRIC TITRATIONS OF SODIUM WITH THALLIUM IODIDE IN LIQUID AMMONIA

Temp. °C.	In reaction vessel	In burette	Point of inflexion ml.	$NaTl_x$ x	Remarks
-65·0	27·12mg.Na in 65 ml.NH_3	428·9mg.TlI in 77·56ml. NH_3	37·08	1·11	Decolorization + 1st inflexion
			49·28	2·23	2nd inflexion
			68·52	32·0	3rd inflexion
-50·0	39·50mg.Na in 80 ml.NH_3	650·8mg.TlI in 75·67ml. NH_3	34·59	1·11	Decolorization + 1st inflexion
			44·40	2·04	2nd inflexion
			64·73	47·0	3rd inflexion

From the 'x' values in the 5th column of Table XLII, it appears that compounds of the composition NaTl and $NaTl_2$ are formed.[11]

On treating a liquid ammonia solution of sodium with a weighed amount of thallous iodide, a reaction occurs immediately with the formation of a metallic precipitate; the blue colour of the sodium solution disappears and a greenish-yellow solution is formed. The composition of the reaction product, which is slightly soluble in ammonia, is Na_3Tl_2.[20]

A metallic precipitate, inactive to air and water, is formed when silver cyanide or iodide is added to a solution of sodium in liquid ammonia, the silver salt being reduced to silver.[20]

No exact or reproducible point of inflexion is obtained when a solution of sodium in liquid ammonia is titrated potentiometrically with a solution of silver iodide in the same solvent. The black precipitate formed is silver.[11]

When a silver salt such as the chloride or iodide is added to a solution of sodium in ammonia, the reaction ratio of sodium to silver salt is 1·00. $Na + AgI \rightarrow NaI + Ag$. The end point, *i.e.* the disappearance of the blue colour of the sodium solution, can be judged precisely and it has been suggested that free sodium in solution can be accurately determined by adding a weighed amount of silver chloride.[26,27]

A black precipitate is formed, and the solution of sodium in liquid ammonia is decolorized, when a potentiometric titration is carried out with a liquid ammonia solution of gold iodide. A point of inflexion is obtained shortly after the solution has been decolorized; the composition of the mixture corresponds to NaAu.[11]

Cuprous iodide is reduced by sodium in liquid ammonia to free copper.[27]

A precipitate of metallic copper with perhaps a slight amount of sodium is obtained when a liquid ammonia solution of sodium is titrated potentiometrically with a solution of copper iodide in the same solvent. The supernatant liquid is decolorized. No reproducible point of inflexion is obtained.[11]

The low solubilities of cadmium iodide and cyanide in liquid ammonia are responsible for the difficulty experienced with the end point when the solution is added to a liquid ammonia solution of sodium. The ratio of Na/Cd found for the precipitate lies between 0·2 and 1·0, many values lying in the range of 0·5. In many cases unchanged salt is found with the precipitated metal at the end of the reaction. It is probable that the higher values for the ratio are correct and not improbable that the compound NaCd is formed. The precipitate is reactive towards air and water.[20]

The following reaction: $(2x + 1)\text{Na} + x\text{CdI}_2 \rightarrow \text{NaCd}_x + 2x\,\text{NaI}$ occurs when a solution of sodium in liquid ammonia is titrated with a liquid ammonia solution of cadmium iodide, potentiometrically. Points of inflexion are observed as shown in Table XLIII.

TABLE XLIII. - POTENTIOMETRIC TITRATIONS OF SODIUM WITH CADMIUM IODIDE IN LIQUID AMMONIA

Temp. °C.	In reaction vessel	In burette	Point of inflexion ml.	NaCd_x x	Remarks
-55·8	25·45mg. Na in 80 ml. NH_3	238·4mg. CdI_2 in 84·17ml. NH_3	65·30	5·23	Decolorization
			66·62	6·77	1st inflexion
			69·36	16·0	2nd inflexion
			70·59	35·00	3rd inflexion
-62·3	45·17mg. Na in 80 ml. NH_3	400·0mg. CdI_2 in 72·05ml. NH_3	60·01	6·29	Decolorization + inflexion
			64·81	Cd	Inflexion

The results indicate that a phase between NaCd_5 and NaCd_7 is formed, as well as reduction of the cadmium salt to cadmium. A finely divided black precipitate is formed during the titration.[11]

An immediate reaction occurs when mercuric iodide or cyanide or mercurous iodide is added to a solution of sodium in liquid ammonia. The solution becomes colourless and the finely divided metal is precipitated. On standing, the supernatant liquid becomes blue again and the decolorization and return of the colour continue as more of the salt is added. Apparently the compound NaHg is first formed but is unstable in ammonia and breaks down to a compound richer in mercury, the freed sodium then dissolving in ammonia. By increasing the amount of salt originally added a permanently colourless solution is obtained and the precipitate has the composition NaHg_2.[20] The compound, NaHg, is formed when ethyl mercuric chloride is reduced by excess sodium in liquid ammonia solution.[20]

Zinc iodide and cyanide are readily reduced by sodium in liquid ammonia. Reaction occurs immediately and a finely divided metallic precipitate is formed which is extremely reactive with air and water. The ratio of sodium to zinc in the compound formed is between 0·24 and 0·289 and corresponds to the composition NaZn_4.[20] Burgess and Rose[28] have verified the existence of the compound NaZn_4 and give the following equation for the reaction: $4\text{Zn(CN)}_2 + 9\text{Na} \rightarrow \text{NaZn}_4 + 8\text{NaCN}$. A slight excess of sodium does not affect the composition of the precipitate. Oxygen is taken up rapidly by the precipitate and much heat is evolved, but the appearance of the compound is not changed. This primary oxidation is followed by a secondary reaction which proceeds at a very slow rate for a long time, the colour of the precipitate changes from black to grey and then to white. Dry air acts in the same way as dry oxygen; moist air or oxygen accelerates the reaction so that the two stages are not apparent. There is no evidence of the formation of peroxides. With dilute acid one mole of the compound NaZn_4 liberates nine equivalents of hydrogen, (*i.e.*, from both the sodium and the zinc present); with water, approximately 4·5 equivalents of hydrogen are liberated in two months.

Potentiometric titrations of a liquid ammonia solution of sodium with a solution of zinc iodide in the same solvent have been carried out by Zintl, Goubeau and Dullenkopf.[11] The reaction is: $(2x + 1)Na + xZnI_2 = NaZn_x + 2x\,NaI$, and details of the titration are given in Table XLIV.

TABLE XLIV. - POTENTIOMETRIC TITRATIONS OF SODIUM WITH ZINC IODIDE IN LIQUID AMMONIA

Temp. °C.	In reaction vessel	In burette	Point of inflexion ml.	$NaZn_x$ x	Remarks
-59·5	74·43mg.Na in 60 ml.NH_3	586·9ml. ZnI_2 in 76·76ml. NH_3	66·85 68·10	11·8 22·0	Decolorization Inflexion
-55·5	35·42mg.Na in 55 ml.NH_3	270·2mg.ZnI_2 in 75·75ml. NH_3	66·33 68·15	12·8 44·0	Decolorization Inflexion

The results indicate the formation of a compound $NaZn_{12}$ or $NaZn_{13}$, but there is no evidence that the compound $NaZn_4$ is formed.

The reaction between metallic tin and a solution of sodium in liquid ammonia takes place slowly; the characteristic blue colour of the sodium solution gradually changes to greenish yellow and finally to a transparent red. The greenish yellow colour is produced no doubt by the presence of a mixture of various constituents in solution.

On adding pellets of stannous iodide to a liquid ammonia solution of sodium until a change from green to red occurs, a compound is formed in which the ratio Na/Sn is 3:8; this corresponds to the formula Na_4Sn. When an excess of stannous iodide is added, the red colour is at first intensified after which metallic tin is precipitated until the solution becomes colourless. The compound Na_4Sn is not stable in solution but breaks down giving free sodium and a compound richer in tin.[20]

Reproducible results cannot be obtained by potentiometric titration of a liquid ammonia solution of stannic sulphide or iodide with sodium in liquid ammonia solution. A deep red solution of the compound Na_4Sn_9 is formed by extracting sodium-tin alloys with liquid ammonia. Titration of this solution with a solution of sodium in the same solvent does not give satisfactory results so that it is impossible to say whether lower polystannides exist.[11]

Manganese iodide, MnI_2, is reduced by sodium in liquid ammonia solution to manganese which catalyzes the reaction between sodium and ammonia and appears to react with the sodamide formed.[27] This reaction may be used to obtain manganese for the preparation of the pure oxide by slow oxidation.[29]

Compounds of sodium with lead are formed when a liquid ammonia solution of sodium is agitated with excess lead at -33°C. They are very soluble in ammonia and separate out without ammonia of crystallization. One gram atom of sodium dissolves 2·26g.-atoms of lead and not four as indicated by the work of Joannis.[30]

In the presence of metallic lead, an equilibrium is assumed to exist between a Pb_2^- ion and another negative ion of the form Pb_3^-. The following equilibrium ratio has been calculated:-

$$(Pb_3^-)/(Pb_2^-) = 0{\cdot}26/0{\cdot}74 = 0{\cdot}36$$

(the molal concentrations of the substances refer to the conditions when 1g.-atom of sodium is present). It is assumed that there are about 3moles of $NaPb_2$ to one mole of $NaPb_3$.[31]

The addition of a lead salt to sodium in liquid ammonia results in the initial formation of the normal plumbide, Na_4Pb, but this compound is unstable and decomposes to give free sodium and a compound richer in lead. An alloy corresponding to NaPb dissolves readily in liquid ammonia to give a green solution; one corresponding in composition to $NaPb_2$ is also soluble and gives a much darker green solution; an alloy of composition Na_2Pb is slightly soluble forming a yellowish green solution.[20]

Potentiometric titrations of a liquid ammonia solution of sodium with a solution of lead iodide in the same solvent show that the following reaction occurs: $(4 + 2x)Na + xPbI_2 \rightarrow Na_4Pb_x + 2x\ NaI$. The data for typical titrations are given in Table XLV.

TABLE XLV. - POTENTIOMETRIC TITRATIONS OF SODIUM WITH LEAD IODIDE IN LIQUID AMMONIA

Temp. °C.	In reaction vessel	In burette	Point of inflexion ml.	Composition of compound
−50·2	15·48mg. Na in 75 ml. NH_3	170·1mg. PbI_2 in 69·72ml. NH_3	49·85 52·26 64·06	Na_4Pb_7 Na_4Pb_9 Pb
−50·2	102·3mg. Na in 75 ml. NH_3	1190·2mg. PbI_2 in 64·77ml. NH_3	- 45·90 55·98	- Na_4Pb_9 Pb
−50·2	271·0mg. Na in 100 ml. NH_3	2992·6mg. PbI_2 in 58·03ml. NH_3	- 43·03 52·63	- Na_4Pb_9 Pb
−50·2	54·46mg. Na in 80 ml. NH_3	622·3mg. Na in 64·24ml. NH_3	43·97 46·70 57·26	Na_4Pb_7 Na_4Pb_9 Pb

The compound, Na_4Pb_7, is not detected in the more concentrated solutions.[11]

The following reactions which occur when sodamide and amalgamated aluminium or magnesium are brought together also occur when a solution of sodium in liquid ammonia reacts with aluminium or magnesium: $Al + 3NaNH_2 \rightleftharpoons Al(NH_2)_3 + 3Na$; $Al(NH_2)_3 + NaNH_2 \rightarrow Al(NH_2)_2NHNa.NH_3$; $3Na + 3NH_3 \rightleftharpoons 3NaNH_2 + 1{\cdot}5H_2$.[32] The reaction between magnesium and liquid ammonia to form magnesium amide, $Mg(NH_2)_2$, is very slow but it is catalyzed by the presence of sodium. Sodium salts may be used in place of sodium: $2NaI + Mg \rightleftharpoons MgI_2 + 2Na$; $2Na + 2NH_3 \leftrightarrow 2NaNH_2 + H_2$; $2NaNH_2 + MgI_2 \rightarrow Mg(NH_2)_2 + 2Na$.[33]

The initial reaction between a liquid ammonia solution of sodium and a suspension of aluminium iodide hexammoniate, $[Al(NH_3)_6]I_3$ at −70°C. is rapid and attended by the immediate discharge of the blue colour of the metal solution, evolution of hydrogen and liberation of heat. The whole of the solid phase originally present at −70°C. passes into solution. The rate of reaction then falls to a very low value not greatly different from that observed for the reaction between metals and liquid ammonia. The proposed course of the reaction is: $[Al(NH_3)_6]^{+++} + NH_3 \rightarrow [Al(NH_3)_5NH_2]^{++} + NH_4^+$. This is the initial reaction. The ammonium ion is destroyed by the metal solution, ammonia and hydrogen being produced: $NH_4^+ + e^- \rightarrow NH_3 + H$. The rapid reaction continues until all the aluminium is bound in a soluble, relatively stable complex of empirical composition $Al(NH_2)_{1\cdot5}I_{1\cdot5}$. The net result is the evolution of hydrogen and the accumulation of amide in solution.[34]

Ammonium azide, NH_4N_3, with sodium in liquid ammonia forms sodium azide, ammonia and hydrogen: $Na + NH_4N_3 \rightarrow NaN_3 + NH_3 + H$. The reaction is vigorous.[35]

Hydrogen is liberated when sodium is added to a liquid ammonia solution of ammonium bromide or iodide.[36-39] The halides behave as acids in relation to ammonia: $2NH_4Br + 2Na \rightarrow 2NaBr + 2NH_3 + H_2$; $2NH_4I + 2Na \rightarrow 2NaI + 2NH_3 + H_2$ and may be used to eliminate excess alkali metal from a reaction mixture or to reduce organic compounds *in situ.* Sodium and sodium sludges may be removed from a liquid metal system by washing with liquid ammonia and liquid ammonia-ammonium chloride.[40] The heats of reaction of the alkali metals with dilute solutions of ammonium bromide and ammonium chloride in liquid ammonia have been measured; from these values and the heats of solution of the alkali metals in liquid ammonia, the heat of reaction of each dilute solution with the ammonium ion has been found to be exothermic and within experimental error identical whether the metal be lithium, sodium, potassium or caesium, *i.e.*, a mean value of 40·4 ± 1 kg.-cal. is obtained. From the measured heats of reaction and corresponding free-energy changes, relative partial molal ionic entropies and entropies of solvation of the alkali metal ions in liquid ammonia have been calculated.[41]

The reaction between sodium and sodium nitrate in liquid ammonia has been examined, in connexion with the explosion which occurs during the electrolysis of sodium nitrate in liquid ammonia. The reaction proceeds in three stages: in the first sodium nitrite is formed, in the second the compound $Na_2N_2O_2$, caustic soda and sodamide are formed, and in the third a yellow explosive substance believed to be disodium nitrite. A similar compound is formed by the action of sodium on sodium nitrate.[42]

Sodium perchlorate and hydrogen are formed when ammonium perchlorate is added to a liquid ammonia solution of sodium; sodium iodate and periodate together with some sodium iodide and hydrogen are formed when the corresponding ammonium salts are treated in the same way.[23]

Neither sodium chlorate nor the perchlorate is reduced by sodium in liquid ammonia at −33°C., nor are they reduced by sodium and ammonium bromide in liquid ammonia.[23]

Sodium bromide, sodium hydroxide and sodamide are formed when sodium bromate is treated with sodium in liquid ammonia, the ratio $Na/NaBrO_3$ being 6/1.[23]

With sodium iodate the reaction with sodium or with sodium and ammonium bromide in liquid ammonia at −33°C. and at room temperature is very slow and incomplete, but some sodium iodide is formed.[23]

The periodate, $Na_2H_3IO_6$, is reduced to $Na_3H_2IO_6$ by sodium in liquid ammonia, while the reaction with the compound, $Na_3H_2IO_6$, is very slow and incomplete with either sodium or sodium and ammonium bromide at −33°C. in liquid ammonia; the product in the latter case is sodium iodide.[23]

There is an initial rapid reaction when potassium permanganate is treated with sodium in liquid ammonia; the products are potassium sodium manganate, $KNaMnO_4$, and manganese oxides.[23]

Sodium nitrite is reduced by sodium in liquid ammonia and a bright yellow precipitate of disodium nitrite, Na_2NO_2, is formed. This substance is very reactive towards moisture, air and carbon dioxide and explosions occur easily. In the pure state, if kept *in vacuo*, it stands moderate heating, but at 100°C. to 130°C. it decomposes violently. When treated with water it gives sodium hydroxide, sodium nitrite and sodium nitrate.[43,44]

Anhydrous nickel, cobalt and copper nitrates, manganous iodide and partially dehydrated ferric nitrate are reduced in liquid ammonia to the metal when sodium is added. With incompletely dehydrated ferric nitrate the reduction is accompanied by the formation of a complex and there is a tendency for the sodium to explode. Instead of adding the sodium piece by piece as long as the reaction proceeds, the method described for the other dehydrated materials, it is better to add ferric nitrate to sodium already dissolved in liquid ammonia when reduction proceeds smoothly. All the precipitated metals become hot enough to glow when the ammonia is removed rapidly by filtering too long on the suction pump, but if air is admitted gradually to an Erlenmeyer flask containing the metals still wet with ammonia, so that slow oxidation occurs by diffusion of air, the pure metallic oxides can be obtained. Manganese is so active that it becomes warm even while it is still wet with ammonia.[29]

The catalytic activity of nickel produced by the reduction of nickel bromide, $NiBr_2$, with liquid ammonia solutions of the alkali metals, is substantially constant per unit area for all the alkali metals. The rates of reaction are too rapid for measurement but they increase from lithium to caesium.[45]

Excess potassium tetracyanonickelate, $K_2Ni(CN)_4$, when treated with sodium in liquid ammonia, gives a bright red precipitate of potassium tricyanonickelate, $K_2Ni(CN)_3$.[46]

A lilac coloured solid, NaCO, is formed when carbon monoxide is led into a liquid ammonia solution of sodium at −50° C. At 90° C. it decomposes according to the equation: $4NaCO \rightarrow Na_2CO_3 + Na_2O + 3C$. When heated in air it explodes.[47]

The addition of ammonium chloride or hydrogen sulphide to the reaction product of sodium and carbon monoxide in liquid ammonia before evaporation of liquid ammonia, results in the formation of substances which are reasonably stable. The final product is a mixture of either the ammonium or sodium salt of rhodizonic acid, glycollic acid amide and glycollic acid. The best yields of rhodizonate and amide, based on the amount of sodium consumed, are obtained when sodium metal is added in small amounts at a time, so that it is only slightly in excess during the reaction, and when oxygen and moisture are excluded. The amide is separated from the reaction products by extraction with dioxan or ether.[48]

The following reactions occur when carbonyls are treated with a liquid ammonia solution of sodium: $[Co(CO)_4]_2 \rightarrow Na[Co(CO)_4]$; $[Fe(CO)_4]_3 \rightarrow Na_2[Fe(CO)_4]$; $Fe(CO)_5$ or $Fe_2(CO)_9 \rightarrow Na_2[Fe(CO)_4] + CO$; $[Co(CO)_3]_4 \rightarrow Na[Co(CO)_4] + Co$; $Fe(CO)_4I_2 \rightarrow Na_2[Fe(CO)_4] + NaI$. The hexacarbonyls of the chromium group and $Ni(CO)_4$ liberate carbon monoxide on reaction but the other products formed are not known.[49]

According to Evers,[50] sodium phosphide, represented empirically as Na_2P but probably present as a dimer, is formed by the reaction of the elements in liquid ammonia. Normal phosphides are not formed under these conditions.

The compound, Na_4P_2, tetrasodium diphosphide, is reduced to sodium dihydrogen phosphide when ammonium bromide is added to a solution of sodium and the tetrasodium compound in liquid ammonia: $Na_4P_2 + 2Na + 4NH_4Br \rightarrow 2NaPH_2 + 4NaBr + 4NH_3$. The formation of the PH_2 ion is shown by its conversion to CH_3PH_2, when the solution is treated with methyl iodide.[51] More recently, however, Royen and Zschaage have stated that when sodium and phosphorus react together in liquid ammonia the product is not $Na_4P_2,2NH_3$ as stated by Evers[50] but a mixture of the two compounds, $Na_2H_2P_2$ and $2NaNH_2$. The reaction with ammonium bromide is considered to be: $Na_2H_2P_2 + 2NaNH_2 + 4NH_4Br + 2Na \rightarrow 2NaPH_2 + 6NH_3 + 4NaBr$. The compound, $Na_2H_2P_2$, does not itself react with sodium.[52]

When a liquid ammonia solution of sodium and a large excess of potassium amide are allowed to stand in contact with a small quantity of platinum black, the metallic sodium is rapidly converted to sodium amide which reacts with potassium amide to form the compound, $NaNK_2,2NH_3$.

The amides of sodium and rubidium are formed separately by the action of liquid ammonia on the metals in the presence of platinum black and when rubidium amide solution is poured upon the slightly soluble sodium amide the latter dissolves forming the compound $NaNHRb,NH_3$ which is obtained in the form of beautiful crystals on concentrating the solution. A compound isolated from the mother liquor is probably dirubidium ammonosodiate, $NaNRb_2,2NH_3$.[53]

The system sodium/sodium iodide/ammonia has been studied by Sienko[54] by measuring the electrical resistance of the solution as a function of decreasing temperature. A discontinuity in the slope of the resistance–temperature curve corresponds to the temperature at which phase separation occurs. The upper critical temperature for the separation into two phases is −41·6° C.

The alkali metals react with a liquid ammonia solution of the diammoniate of diborane, $B_2H_6,2NH_3$, and on removal of the solvent yield the alkali metal borohydride and aminoborine: $Na + B_2H_6 2NH_3 \rightarrow NaBH_4 + BH_2NH_2 + NH_3 + 0{\cdot}5H_2$. Sodium borohydride is soluble in ethylene glycol dimethyl ether and is separated from the reaction products by extraction with this solvent. *X*-Ray diffraction patterns have been obtained for the soluble and insoluble portions of the reaction products and the only crystalline substance is sodium borohydride in the soluble portion. The amide, BH_2NH_2, undergoes ammonolysis during the removal of the solvent ammonia, to an extent that is greatest with lithium and least with potassium.[55]

When carbon disulphide is dropped into sodium in liquid ammonia and the brown product methylated with dimethyl sulphate the following compounds are obtained: dimethyldithiondithioloxalate, $(CS_2CH_3)_2$, an isomer of this substance, the compounds $(CH_3)_2CS_3$ and $C_6H_{12}S_4$ and dimethyl sulphide.[56]

Liquid ammonia solutions of the compound BF_3,NH_3 have been titrated with solutions of sodium in the same solvent in an apparatus which permits the quantitative recovery of all the products. The following equation expresses the results obtained: $5Na + 2BF_3,NH_3 + 2NH_3 \rightarrow 5NaF + (NH_2)_2\text{-}BNHB(F)NH_2 + 2{\cdot}5H_2$.[57]

Reviews of the reactions of sodium in liquid ammonia with numerous references are given by Fernelius and Watt[58] and by Watt.[23]

Reactions of sodium in liquid ammonia

B. Organic Reactions in Liquid Ammonia.

A review of the reactions of organic and organometallic compounds with solutions of sodium in liquid ammonia with numerous references has been given by Watt.[1]

Saturated hydrocarbons do not appear to react and in fact, reducible substances contaminating hydrocarbons may be removed by treatment with sodium in liquid ammonia.

Diphenylmethane reacts slowly at room temperature to give the sodium derivative, $(C_6H_5)_2CHNa$, in small amounts, and on oxidation this derivative yields sodium peroxide and *sym.*-tetraphenylethane; $2(C_6H_5)_2CHNa + O_2 \rightarrow Na_2O_2 + (C_6H_5)_2CHCH(C_6H_5)_2$. Triphenylmethane reacts slowly with sodium in liquid ammonia at $-33{\cdot}5^\circ$C. to give the sodium derivative, $(C_6H_5)_3CNa$.[1,2]

p-Benzohydryltetraphenylmethane, $(C_6H_5)_2CHC_6H_4C(C_6H_5)_3$, is stable in a liquid ammonia solution of sodium, butadiene gives butene and octadiene, whilst isoprene gives a 60% yield of 2-methyl-2-butene together with high molecular weight hydrocarbons. Alloöcimene, $(CH_3)_2C{=}CHCH{=}CHC(CH_3){=}CHCH_3$, yields 2:6-dimethyl-3:5-octadiene.[1]

The reduction of phenylated olefines has been studied by Wooster and Ryan.[3] In no case is the phenyl group attacked by the alkali metal but the double bonds in the side chain may become saturated; after decomposition of the sodium derivative with ammonium chloride, the corresponding phenylated paraffin is obtained. The stable organo-sodium derivatives react with oxygen and certain RX compounds such as ethyl bromide, dimethyl sulphate and benzyl chloride. Sodium also reacts with some of the olefines causing polymerization, dimerization, cleavage of carbon–carbon bonds and addition to but one of two double bonds in a molecule. The following reactions are described: styrene, $C_6H_5CH{=}CH_2$ → 50% of ethylbenzene and polymers; stilbene, $C_6H_5CH{=}CHC_6H_5$ → dibenzyl; *unsym.*-diphenylethylene → the sodium derivative, $(C_6H_5CNaCH_2)_2$, which is hydrolyzed by ammonium chloride to 1:1-diphenylethane and a small amount of 1:1-2:2-tetraphenyl butane, $[(C_6H_5)_2CHCH_2]_2$; triphenylethylene, $(C_6H_5)_2C{=}CHC_6H_5$, adds two atoms of sodium; tetraphenylethylene, $(C_6H_5)_2C{=}C(C_6H_5)_2$ gives a disodium compound stable in ammonia; with excess sodium and ethyl bromide, *sym.*-tetraphenylethane, $[(C_6H_5)_2CH]_2$ and diphenylethylmethane, $(C_6H_5)_2CHC_2H_5$ are formed, indicating cleavage followed by reaction with the bromide and ammonolysis; 1:1-diphenylpropene, $(C_6H_5)_2C{=}CHCH_3$ reacts readily with sodium in liquid ammonia, the primary addition product being semi-ammonolyzed; the stable products with ammonium chloride and benzyl chloride respectively are diphenylethyl ethane, $(C_6H_5)_2$-CHC_2H_5, and diphenylbenzylethylmethane, $(C_6H_5)_2C(CH_2C_6H_5)C_2H_5$. 1:1-3:3-Tetraphenylpropene, $(C_6H_5)_2C{=}CHCH(C_6H_5)_2$, reacts with two atoms of sodium and on hydrolysis with ammonium chloride forms 1:1-3:3-tetraphenylpropane; the stable red addition products with dimethyl sulphate, ethyl bromide and benzyl chloride give 1:1-3:3-tetraphenylbutane, 1:1-3:3-tetraphenylpentane and 1:1-3:3-4-pentaphenylbutane respectively. Tetraphenylpropadiene, $(C_6H_5)_2C{=}C{=}C(C_6H_5)_2$, reacts with about four atoms of sodium and on evaporation of the liquid ammonia an almost quantitative yield of 1:1-3:3-tetraphenylpropane, $(C_6H_5)_2CHCH_2CH(C_6H_5)_2$, is obtained.

Neither 1-hexene nor 2-*cyclo*propyl-1-pentene is affected by sodium in liquid ammonia, nor by sodium and ammonium bromide in the same solvent. They are, however, reduced to hexane and 2-*cyclo*propylpentane if methyl alcohol is present.[4]

Two examples are given of partial reduction of diene hydrocarbons with a conjugated double bond system by means of sodium in liquid ammonia; thus 2:4-hexadiene affords 60–65% of 2-hexene and 35–40% of 3-hexene, with about 30% of *cis* and 70% of *trans* isomers,[5] whilst 2:5-dimethyl-2:4-hexadiene gives 73% of 2:5-dimethyl-2-hexene.[6] Other similar reactions have been described by the same authors.

2:3-Dimethyl-1:3-butadiene is reduced by sodium in liquid ammonia giving chiefly 2:3-dimethyl-2-butene with a small amount of 2:3-dimethyl-1-butene. Similar reduction of 2:4-dimethyl-1:3-pentadiene yields 2:4-dimethyl-2-pentene. 2-Methyl-2:4-pentadiene gives 50% of 2-methyl-3-pentene and about 8% of material which contains some 2-methyl-2-pentene.[7]

Sodium acetylide is formed when acetylene is passed into solutions of sodium in liquid ammonia at its normal boiling point. Some of the acetylene is reduced to ethylene, but this may be avoided by adding sodium to the liquid ammonia at such a rate that there is never any appreciable excess of sodium present.[8,9]

Monoalkylacetylenes react with sodium and liquid ammonia in the following manner: $2CH_3C{\equiv}CH + 2Na \rightarrow 2CH_3C{\equiv}CNa + 2H$; $CH_3C{\equiv}CH + 2H \rightarrow CH_3CH{=}CH_2$. About two thirds is metalated and one third hydrogenated. The addition of an ammonium salt to the reaction mixture results in complete reduction and high yields of the corresponding olefines are obtained. Dialkylacetylenes on reduction with sodium in liquid ammonia give good yields of the *trans* form of the corresponding olefine. For example, reduction of 3-octyne and 4-octyne gives 98% yields of *trans*-3-octene and *trans*-4-octene respectively.[1] Attempts to reduce di*tert.*-butylacetylene to the *trans*-olefine have been unsuccessful.[10]

Diacetylenes are reduced by sodium or by sodium and ammonium sulphate in liquid ammonia to the corresponding *trans-trans* dienes; a 72% yield of 2:7-nonadiene, without evolution of hydrogen, and a 61% yield of 1:6-heptadiene are obtained from 2:7-nonadiyne and 1:6-heptadiyne respectively.[1]

Phenylacetylene is reduced by sodium in liquid ammonia to its sodium derivative and ethylbenzene: $3C_6H_5C{\equiv}CH + 4Na + 2NH_3 \rightarrow 2C_6H_5C{\equiv}CNa + C_6H_5C_2H_5 + 2NaNH_2$.[11]

The benzene nucleus is not attacked by sodium in liquid ammonia and in fact benzene, toluene and xylene may be used as solvents for reactions between sodium and many organic compounds in liquid ammonia.[1]

2:5-Dihydrotoluene is reduced to give 50% of 1-methyl*cyclo*hexene and 10% of 3-methyl*cyclo*hexene.[12] Biphenyl is reduced by sodium in liquid ammonia to tetrahydrobiphenyl[1] and at −75° C. to −70° C. to the 3:4-dihydroderivative. Further reaction with sodium yields the 3:4:5:6-tetrahydrobiphenyl. Terphenyl is reduced to a 3:4-dihydroderivative and a compound isomeric with terphenyl but containing no reactive double bond.[13]

Tetrahydronaphthalene and sodium amide are formed when naphthalene is reduced with sodium in liquid ammonia. The bright red solution formed when the reaction is carried out at −33° C. or at lower temperatures is due to the presence of an unstable intermediate compound, the 1:2:3:4-tetrasodium addition product, which is three-fourths ammonolyzed. A green colour which changes to orange-red and finally to red is produced when naphthalene is dissolved in ether and treated with sodium in liquid ammonia at −75°C. to −60° C. On treatment with methanol, Δ^2-dihydronaphthalene is formed. At the boiling point of liquid ammonia, the Δ^1-isomer is formed; at −60° C. the Δ^2-isomer in ether on treatment with sodium and liquid ammonia is converted to the Δ^1-isomer; at −50° C. it is reduced with sodium to tetralin.[1,14]

Naphthalene, sodium and *iso*butyl chloride in liquid ammonia yield 1:2:3:4-tetrahydro-1:4-di-*iso*butylnaphthalene and a little tetralin.[1,15] Anthracene is reduced by sodium in liquid ammonia to 9:10-dihydroanthracene, 9:10-diphenylanthracene to the 9:10-dialkali salt, phenanthrene to 1:2:3:4-tetrahydrophenanthrene, and dimethylfluorene to tetrahydrodimethylfluorene. Fluorene and indene give sodium salts by substitution accompanied by some hydrogenation. The addition of ammonium bromide to sodium and liquid ammonia does not cause more extensive hydrogenation of naphthalene, biphenyl, acenaphthene and phenanthrene than occurs when sodium and liquid ammonia alone are used but fluorene is more extensively hydrogenated and anthracene also, the latter yielding 1:2:3:4-tetrahydroanthracene and other products.[1]

The presence of methanol or ethanol with sodium in liquid ammonia brings about the following reactions: benzene → 1:4-dihydrobenzene, 83%[1] toluene → 2:5-dihydrotoluene, 83%[1,12] xylene (mixture) → dihydroxylenes, 87%;[1] *m*-xylene → 2:5-dihydro-*m*-xylene; *p*-xylene → 2:5-dihydro-*p*-xylene;[16] 4:5-dihydro-*m*-xylene → 1:3-dimethyl*cyclo*hexene;[12] *p*-cymene → *γ*-terpinene;[16] 1:4-dihydronaphthalene → tetrahydronaphthalene, not tetralin;[1] tetralin → 1:2:3:4:5:8-hexahydronaphthalene 91%.[1,16]

The following compounds do not react with sodium in liquid ammonia: terpinene, terpinolene, carvene, α-pinene, menthene, 1:3-dimethyl*cyclo*hexene, 2:4-dimethyl*cyclo*hexene, *D*-limonene, *D*-sylvestrene, methylgeraniolene, 4-methyl*cyclo*hexene.[1]

The halogens are usually quantitatively removed from halogen organic compounds by treatment with sodium in liquid ammonia; an analytical method is thus provided for the determination of halogens in organic compounds. The monohalogen substitution products of the paraffin hydrocarbons react to form hydrocarbons both saturated and unsaturated, sodium halides and sodium amide. A number of such reactions are given in Table XLVI taken from Watt's review.[1]

Refs. p. 531

TABLE XLVI. - REACTIONS OF ALKYL HALIDES WITH SOLUTIONS OF SODIUM IN LIQUID AMMONIA

Halide	Products
CH_3Cl	CH_4, CH_3NH_2, $NaCl$
CH_3I	CH_4, CH_3NH_2, NaI
C_2H_5Br	C_2H_6, $NaNH_2$, $NaBr$
C_2H_5I	C_2H_6
C_2H_5I	C_2H_6, $C_2H_5NH_2$, NaI
C_2H_5I	C_2H_6(75%), C_2H_4(4%)
C_2H_5I	$C_2H_5NH_2$(21%), $NaNH_2$
n-C_3H_7Cl	C_3H_8, C_3H_6(trace), $NaNH_2$
n-C_3H_7I	C_3H_8
n-C_3H_7I	C_3H_8, $C_3H_7NH_2$, NaI
n-C_3H_7I	C_3H_8(71%), C_3H_6(7%), $C_3H_7NH_2$(21%), $NaNH_2$
n-C_4H_9Cl	C_4H_{10}, $NaNH_2$, $NaCl$
iso-C_4H_9Cl	C_4H_{10}, C_4H_8(trace), $NaNH_2$
iso-C_4H_9I	C_4H_{10}(70%), C_4H_8(15%), $C_4H_9NH_2$(15%), $NaNH_2$
iso-$C_5H_{11}Cl$	C_5H_{12}, C_5H_{10}(trace), $NaNH_2$
iso-$C_5H_{11}I$	C_5H_{12}, C_5H_{10}(trace), $NaNH_2$
tert.-$C_5H_{11}I$	*sec.*-C_5H_{12}(and explosion)
$C_2H_5CHI(CH_2)_2CH_3$	C_6H_{14}, C_6H_{12}(trace), $NaNH_2$
$CH_3(CH_2)_5CHICH_3$	C_8H_{18}, $NaNH_2$

The reaction of methyl iodide is complicated since it reacts with liquid ammonia forming ammonium iodide which is acted on by sodium: $4CH_3I + 4NH_3 \rightarrow (CH_3)_4NI + 3NH_4I$.

Butyl bromide reacts quantitatively with sodium in liquid ammonia and the reaction has been used to determine sodium in sodium hydride. A liquid ammonia solution of sodium is titrated with butyl bromide dissolved in *n*-hexane.[17]

meso- and *dl*-2:3-Dibromobutane with sodium in liquid ammonia yield the same mixture of *cis*- and *trans*-2-butene, but 50% *meso*- 50% *dl*- 1:2-dibromo-1:2-dideuteroethane yields slightly different mixtures of *cis*- and *trans*-1:2-dideuteroethylene. The authors discuss debrominations with sodium in liquid ammonia in terms of a free radical mechanism.[18]

Reactions of phenyl-substituted alkyl halides with sodium in liquid ammonia[1] are shown in Table XLVII.

TABLE XLVII. - REACTIONS OF PHENYL-SUBSTITUTED ALKYL HALIDES WITH SODIUM AND LIQUID AMMONIA

Halide	Products
$PhCH_2Cl$	$PhCH_3$, $PhCH_2CH_2Ph$, and a solid hydrocarbon
$PhCH_2Br$	$PhCH_2CH_2Ph$
Ph_2CHCl	$Ph_2CHCHPh_2$(66%), Ph_2CH_2(28%)
$Ph_3C.Cl$	Ph_3CNa
$PhCHCl_2$	$PhCH_2CH_2Ph$(7%), $PhCH_2NH_2$(38%)
$Ph_2C.Cl_2$	$Ph_2C{=}CPh_2$(90%)
$PhC.Cl_3$	$PhCH_2CH_2Ph$(5%), nitrogenous substance
$PhCH_2CH_2Br$	PhC_2H_5(38%), $PhCH{=}CH_2$(1·3%)
Ph_3CCH_2Cl	Ph_2CNaCH_2Ph
$Ph_3CCH_2CH_2I$	Ph_3CNa, C_2H_4
$Ph(CH_2)_3Br$	PhC_3H_7(28%), $Ph(CH_2)_3NH_2$(18%)
$Ph(CH_2)_4Br$	PhC_4H_9(43%), $Ph(CH_2)_4NH_2$(17%), other hydrocarbons and amines
$PhC(CH_3)_2CH_2Cl$	$PhC(CH_3)_3$

Acetylene dibromide yields on treatment with sodium in liquid ammonia, sodium acetylide and acetylene.[2]

The monobromo-olefines with sodium and liquid ammonia give principally the corresponding acetylenes and olefines. The acetylene/olefine ratios for 1-bromo-1-propene, 1-bromo-octene, 1,1-dibromo-1-propene and 1-1-dibromo-1-octene are 0·012, 0·45, 0·81 and 1·80 respectively.[1,19]

β-Bromostyrene in dry ether and liquid ammonia slowly treated with sodium in liquid ammonia gives 96% of phenylacetylene; α-chlorostyrene gives 15% of phenylethane; *p*-methyl-α-chlorostyrene gives 63% of tolylacetylene; stilbene dibromide with 15moles of sodium gives 73% of bibenzyl; styrene dibromide yields 66% of phenylacetylene and 2-bromo-1-decene gives 56% of 1-decene. The acetylenes prepared in this way are contaminated with hydrogenation products.[20]

The reactions of paraffin polyhalides with sodium and liquid ammonia have been summarized by Watt,[1] and are given in Table XLVIII.

TABLE XLVIII. - REACTIONS OF PARAFFIN POLYHALIDES WITH SODIUM IN LIQUID AMMONIA

Halide	Products
CH_2Cl_2	CH_4(55%), $NaNH_2$, NaCl
$CHCl_3$	CH_4, $NaNH_2$, NaCl, small amounts of C_2H_4, C_2H_2, NaCN
CHI_3	CH_4, NaI, some C_2H_4, C_2H_2, NaCN, H_2 and N_2
CCl_4	CH_4, NaCl, NaCN, small amounts of N_2
CH_2ClCH_2Cl	C_2H_4, NaCl
CH_3CHCl_2	C_2H_6(51%), C_2H_4(5%), $NaNH_2$
C_2Cl_6	NaCN(not confirmed)
$CH_3CH_2CHCl_2$	C_3H_8, some C_3H_6
$CH_3CCl_2CH_3$	C_3H_8(64%), C_3H_6(14%), $NaNH_2$, NaCl
$CH_3CHBrCH_2Br$	C_3H_6, NaBr
$(CH_3)_2CBrCH_2Br$	C_4H_8, NaBr
$C(CH_2Br)_4$	$C(CH_2NH_2)_4$(small amounts)

Chlorobenzene and iodobenzene react with sodium in liquid ammonia to give benzene, diphenylamine, triphenylamine and sodium halide. A small quantity of aniline is also formed.[1]

A 50% yield of *sec.*-butylbenzene and a 10% yield of *p-sec.*-butylaniline are obtained when *p-sec.*-butylchlorobenzene is treated with sodium in liquid ammonia.[1] The following reaction occurs with *o*- and *p*-chlorotoluenes: $C_6H_4CH_3Cl + 2Na + NH_3 \rightarrow C_6H_5CH_3 + C_6H_4NH_2CH_3 + 2NaCl$.[2] A nitrogen containing residue and *o*-xylene are formed slowly when *o*-bromoxylene reacts with sodium in liquid ammonia.[1] The reaction of *o*-dichlorobenzene with sodium and liquid ammonia is as follows: $2C_6H_4Cl_2 + 4Na + 2NH_3 \rightarrow C_6H_6 + C_6H_4(NH_2)_2 + 4NaCl$.[2] α-Iodonaphthalene is reduced to naphthalene by the action of sodium in liquid ammonia. Indene bromohydrin with sodium and liquid ammonia gives a 75% yield of 2-indanol.[1]

Alkoxides are formed and hydrogen is evolved when alcohols react with sodium in liquid ammonia. Secondary and tertiary alcohols react more slowly than primary alcohols and form more soluble alkoxides. In many cases compounds of the type RONa.ROH are formed. With di- and poly-hydric alcohols, usually only one of the hydrogen atoms is replaced by sodium.

Salts of this type have been treated with alkyl halides or other alkylation agents to produce a variety of ethers.[1]

The reactions listed in Table XLIX have been described by Chablay.[21]

Many other references to similar reactions are given by Watt.[1]

Phenols react with solutions of sodium in liquid ammonia in the same way

TABLE XLIX. - REACTIONS OF ALCOHOLS WITH SODIUM IN LIQUID AMMONIA

Alcohol	Product
Methyl alcohol	CH_3ONa
Ethyl alcohol	C_2H_5ONa
*iso*Butyl alcohol	*i*-C_4H_9ONa
*iso*Amyl alcohol	*i*-$C_5H_{11}ONa$
Ethylene glycol	CH_2OH-CH_2ONa
Glycerol	Monosodium salt
Erythritol	$CH_2OH(CHOH)_2CH_2ONa$
Mannitol	$CH_2OH(CHOH)_4CH_2ONa$
Allyl alcohol	$CH_2{=}CHCH_2ONa$, C_3H_6, NaOH, NH_3
Geraniol	$C_{10}H_{17}ONa$, $C_{10}H_{18}$, NaOH, NH_3
Citronellol	$C_{10}H_{19}ONa$, H, NH_3
Linalol	$C_{10}H_{17}ONa$, $C_{10}H_{18}$, NaOH, NH_3
Cinnamic alcohol	C_9H_9ONa, $C_9H_{11}ONa$, C_9H_{10}, NaOH, NH_3

TABLE L. - REACTIONS OF PHENOLS WITH SODIUM IN LIQUID AMMONIA

Compound	Products
Phenol	C_6H_5ONa
2:4:6-Tri-*tert.*-butylphenol	Monosodium salt
Resorcinol	$C_6H_4(OH)ONa$ (very soluble) $C_6H_4(ONa)_2$
α-Naphthol	$C_{10}H_7ONa$ and traces of 5:8-dihydro-α-naphthol
β-Naphthol	$C_{10}H_{11}ONa$

as the aliphatic alcohols, but the naphthols are in part reduced to tetrahydronaphthols. Some examples are given in Table L.

Alcohols, phenols and naphthols in liquid ammonia are reduced by the hydrogen generated by the action of sodium on ethanol; e.g., benzyl alcohol yields toluene, phenylmethylcarbinol forms ethylbenzene, furfuryl alcohol gives 2:methylfuran.[1]

Aromatic ethers are acted upon by sodium in liquid ammonia according to the equation: $ROR^1 + 2Na + NH_3 \rightarrow RONa + R^1H + NaNH_2$.

The reduction of ethers by sodium and ethanol or methanol in liquid ammonia is also described by Watt; anisole gives Δ^2-*cyclo*hexenone, methylenedioxybenzene yields phenol, 3:4-methylenedioxytoluene forms *p*-cresol. Numerous other reactions are given with references.[1] Wooster has obtained a 60% yield of dihydroanisole from anisole, sodium and methanol in liquid ammonia.[22]

2-Methyl-2-phenyl-1:3-dioxolan and the *o*-, *m*-, *p*-methoxy derivatives on treatment with sodium and methanol in liquid ammonia yield ethylbenzene and the corresponding ethylanisoles which can undergo further reduction in the aromatic nucleus. 2-Methyl-2-phenyl-1:3-oxathiolan is completely hydrogenolyzed.[23]

The cleavage of diphenyl ether derivatives by sodium in liquid ammonia is described by Tomita *et al.*[24] 6:3:4-Bromomethylenedioxyphenoxybenzene, $Br(CH_2O_2)C_6H_2OC_6H_5$, in ether yields a small amount of a strong phenolic substance and a larger amount of a weak phenolic substance, 6:4-$CH_3(HO)C_6H_3$-OC_6H_5. Excess sodium is ineffective in the cleavage of the ether linkage of diphenyl ethers. The presence of the phenolic group in *o*-, *m*- and *p*-hydroxyphenoxybenzene, $HOC_6H_4OC_6H_5$, hinders cleavage of the ethers with sodium in liquid ammonia. 1-Naphthyl phenyl ether and 2-naphthyl phenyl ether are cleaved by sodium in liquid ammonia into phenol and naphthalene or naphthol and benzene but 1:2-dinaphthyl ether, 1-dinaphthyl ether and 2-dinaphthyl ether give resinous substances.[25]

Most aldehydes react readily with ammonia itself. Acetals are usually unaffected by liquid ammonia or by solutions of metals in liquid ammonia.

Only a few reactions have been studied using ketones with sodium solutions in liquid ammonia. The product from acetone has not been identified; benzophenone forms a monosodium ketyl, $(C_6H_5)_2CONa$, with one equivalent of sodium and a disodium ketyl with two equivalents, $(C_6H_5)_2CNaONa$.

Benzophenoneanilide with sodium in liquid ammonia followed by treatment with ammonium bromide gives diphenylmethane and aniline.[1]

Esters react with sodium in liquid ammonia in the following way: $3RCOOR^1 + 4Na + 4NH_3 \rightarrow 2RCONH_2 + RCH_2ONa + 3R^1ONa + 2NH_3$, where $RCOOR^1$ may be ethyl acetate, methyl butyrate, methyl *iso*valerate, ethyl caproate or methyl caprylate. Esters dissolved in ethyl alcohol and treated with sodium in ammonia at −80°C. react as follows: $RCOOR^1 + 2C_2H_5OH + 4Na \rightarrow RCH_2ONa + 2C_2H_5ONa + R^1ONa$; methyl *n*-butyrate, *iso*valerate, heptylate and ethyl caproate yield butanol, *iso*amyl alcohol, heptanol and hexanol on further treatment with water.[21]

Sodium acetate does not react with sodium in liquid ammonia but sodium benzoate is reduced to sodium dihydrobenzoate; dihydro-α-naphthoic acid may be obtained by reducing the sodium salt of α-naphthoic acid with sodium in liquid ammonia.

Carbohydrates react with sodium in liquid ammonia to give sodium salts; the temperature does not appear to be critical and can, in fact, be varied from −80°C. up to room temperature. Cellulose may be converted to the mono-, di-, or tri-sodium salt, depending upon the amount of sodium used, and the salts so obtained are used to form cellulose ethers, xanthates and other derivatives. The formation of tri-sodium cellulose is catalyzed by sodium halogenides. Glucose, fructose, α-methylglucoside, glycogen, inulin, soluble starch, lichenin and chitin yield monosodium salts.[1]

The cleavage of lignin with sodium in liquid ammonia has been investigated.[26-28] Dihydroeugenol, 1-(4-hydroxy-3:5-dimethoxyphenyl) propane and lignin have been extracted from the reaction products obtained by treating aspen lignin with sodium in liquid ammonia.[26] Colourless, fibrous cellulose, dihydroeugenol and other unidentified materials have been isolated from the crude products formed by treating fir lignin with sodium in liquid ammonia.[27]

Aliphatic amines do not usually react with sodium in liquid ammonia; this solvent is not a suitable medium for reduction of the above compounds which give sodium salts readily ammonolyzed by ammonia: $RNHNa + NH_3 \rightarrow RNH_2 + NaNH_2$.

Triphenylmethylamine is converted to sodium triphenylmethide and sodium amide on treatment with sodium and liquid ammonia: $(C_6H_5)_3CNH_2 + 2Na \rightarrow (C_6H_5)_3CNa + NaNH_2$. Although aniline, ethylaniline, *o*-toluidine and diphenylamine do not react with sodium in liquid ammonia at −40°C. the monosodium salt may be formed by carrying out the reaction in an autoclave at room temperature. Slow reduction of aniline with sodium in liquid ammonia in the presence of methyl alcohol results in the formation of tetrahydroaniline; rapid reduction yields 2:5-dihydroaniline.[1]

Although methyl-2:2:6-trimethyl*cyclo*hexyl ketimine and phenyl-2:2:6-trimethyl*cyclo*hexyl ketimine are not reduced by sodium amalgam in ethyl alcohol, they are reduced with sodium in liquid ammonia yielding α-methyl-2:2:6-trimethyl*cyclo*hexanemethylamine and α-phenyl-2:2:6-trimethyl*cyclo*hexanemethylamine respectively.

The reduction of allylamines with sodium in liquid ammonia and alcohol has been studied by King.[29] *N*-Allylpiperidine is reduced to *N*-propylpiperidine; *N*-methallylpiperidine and diethylmethallylamine to the corresponding saturated compounds. The following compounds are unaffected by sodium in liquid ammonia; *N*-crotyl-, -2-*tert.*-butyallyl-, -1-*cyclo*hex-2^1-enyl-, -benzyl- and -2:3:4:5-tetrahydrobenzylpiperidine.

Acid amides react as monobasic acids with sodium in liquid ammonia to give sodium salts and hydrogen. Acetamide, propionamide, butyramide and *iso*valeramide react rapidly; part of the amide is reduced to the corresponding alkoxide. Higher homologues such as caproamide and caprylamide react slowly because of their low solubility in liquid ammonia.[21] Formamide reacts with sodium in liquid ammonia to give the sodium salt, and on further treatment with methyl methacrylate it forms monomethacrylformamide. At −33°C. benzamide is reduced to dihydrobenzamide and benzyl alcohol; sodium *N*-phenylsulphamate is converted to the disodium salt; urea and monosubstituted ureas readily form monosodium salts which are used for synthesizing substituted ureas.[1]

Amino acids are converted to their sodium salts on treatment with sodium in liquid ammonia at low temperatures. Cystine is reduced to cysteine at −33·5°C.: $S_2(CH_2CHNH_2COOH)_2 + 4Na \rightarrow 2NaSCH_2CHNH_2COONa$. Small amounts of sodium sulphide and alanine are also formed. Reactions such as these are used in the synthesis of amino acids and their derivatives; racemization does not occur and optically active derivatives of active substances may be obtained from intermediate sodium salts.[1]

The biscoclaurine alkaloids are reduced in almost quantitative yields to the optically active coclaurine bases with sodium in liquid ammonia.[30,31] The above reaction has also been applied to 3-bisbenzyl*iso*quinoline.[32] The cleavage of O-methylrepandine in toluene by sodium in liquid ammonia yields phenolic and non-phenolic bases.[33] Thebaine is reduced to dihydrothebaine-ϕ; dihydrothebaine on further reduction with sodium in liquid ammonia yields dihydrothebainone-Δ^5-enol methyl ether.[34] Pheanthine or bebeerine dimethyl ether is reduced to a non-phenolic base,[35] *l*-N-methylcoclaurine. The tosyl group in tosyl-L-glutaminyl-L-asparagine and tosyl-L-glutamine is removed with sodium in liquid ammonia. The cation-exchange resin, 'Dowex-50', is used to remove excess sodium from liquid ammonia in these reactions.[36]

α-Tolunitrile gives a sodium derivative with sodium in liquid ammonia: $C_6H_5CH_2CN + Na \rightarrow C_6H_5CHNaCN$ (or $C_6H_5CH = CNNa$) $+ 0{\cdot}5H_2$. Some toluene and sodium cyanide are also formed.[37]

Nitrosoguanidine yields cyanamide and nitrogen on treatment with sodium in liquid ammonia; nitrosobenzene forms disodium phenylhydroxylamine: $PhNO + 2Na \rightarrow PhNNaONa$. Nitroguanidine behaves in the same way as nitrosoguanidine but if ammonium chloride is present aminoguanidine is formed. The nitroparaffins, nitroethane, 1-nitropropane, 2-nitropropane, 1-nitrobutane and 2-nitrobutane, are slowly but incompletely reduced by sodium in liquid ammonia to alkyl hydroxylamines. The products obtained by the reduction of nitrobenzene with sodium in liquid ammonia depend upon the experimental conditions, and the following products have been reported: disodium phenylhydroxylamine, disodium anilide, (with excess sodium); azobenzene (on subsequent addition of excess ethyl bromide); azoxybenzene and azobenzene on subsequent addition of water; aniline with ammonium bromide or methanol.

A 97% yield of dihydro-1-naphthylamine is obtained by treating 1-nitronaphthalene with sodium in liquid ammonia; when the reaction is carried out using toluene as co-solvent, and in the presence of ammonium bromide, 1-naphthylamine is produced. If methanol is used in place of ammonium bromide, a mixture of di- and tetra-hydro-1-naphthylamines is formed. Tetrahydro-2-aminofluorene in 89% yield is produced when 2-nitrofluorene is treated with sodium in liquid ammonia. The addition of ammonium bromide to sodium in liquid ammonia prevents any action with 2-nitrofluorene whereas methanol added in place of ammonium bromide causes the compound to be reduced to a mixture of tetra- and hexa-hydro-2-amino fluorenes.[1]

Azoxybenzene is reduced by sodium in liquid ammonia to azobenzene which is itself reduced to the disodium salt of hydrazobenzene: PhN = NPh + 2Na → PhN(Na)N(Na)Ph. Azobenzene and 2g.-atoms of sodium followed by excess of ethyl iodide yields *sym.*-diethylphenylhydrazine. With 4g.-atoms of sodium, the same product together with ethane and ethylamine is formed. Sodium in liquid ammonia with ammonium bromide reduces azobenzene to aniline. Phenylhydroxylamine is reduced to aniline with sodium and liquid ammonia. $PhNHOH + 2Na + NH_3 \rightarrow PhNH_2 + NaOH + NaNH_2$. Phenylhydrazine is reduced to its monosodium salt which reacts with alkyl halides to form alkylphenylhydrazines. A number of reactions of substituted hydrazines in liquid ammonia sodium solutions are listed by Watt,[1] and references are given. The N–N bond is ruptured by sodium and ammonium bromide in liquid ammonia; if two phenyl groups or one phenyl and another group are attached to the same nitrogen atom, the N–N bond is ruptured by sodium in liquid ammonia alone, *i.e.*, without the addition of ammonium bromide, the hydrogen liberated by replacement with sodium reducing the N–N bond.

Pyrrole is not effectively reduced by sodium and ammonium bromide in liquid ammonia. Indole is reduced to 2:3-dihydroindole, carbazole to 1:4-dihydrocarbazole. When ammonium bromide is present carbazole also forms 1:2:3:4-tetrahydrocarbazole. Sodium and liquid ammonia alone have no action on *N*-methylcarbazole, but with ammonium bromide present, dihydro-*N*-methylcarbazole is formed. The reduction of triazoles with sodium or sodium and ammonium bromide in liquid ammonia has been described in detail by Watt[1] and a number of reactions tabulated. The hydrogen displaced from 1:2:3-benzotriazole reduces the benzenoid ring, while that formed by the action of sodium and ammonium ions reduces the heterocyclic ring. Many reactions of heterocyclic compounds with liquid ammonia solutions of sodium are given by Watt.[1]

The sulphur compounds, thiourea, benzoyl sulphimide, acetone diethyl sulphone, diphenyl sulphone, dinitrophenyl thiocyanate, benzenesulphonamide, benzenesulphonyl chloride, *n*-propyl *p*-toluenesulphonate, *p*-toluenesulphonic acid and 2-naphthylamine-5:7-disulphonic acid, react with sodium in liquid ammonia to form sodium sulphide and/or sodium sulphite. After oxidizing the sodium salts with sodium peroxide, barium sulphate may be precipitated and thus a method provided for the estimation of sulphur in these compounds. Sodium mercaptides are formed by the reaction of alkylmercaptans and phenylmercaptan with sodium in liquid ammonia. An 87·5% yield of dithiopentaerythritol, $(CH_2OH)_2C(CH_2SH)_2$, is obtained by the reduction of 4:4-*bis*hydroxymethyl-1:2-dithia*cyclo*pentane with sodium in liquid ammonia. Aliphatic sulphides (such as ethyl, *n*-propyl and *n*-heptyl) react with sodium in liquid ammonia according to the equations: $R_2S + 2Na + NH_3 \rightarrow RSNa + RH + NaNH_2$ and $2R_2S + 2Na \rightarrow 2RSNa + RR$. The first reaction is the chief one. Aliphatic disulphides are reduced quantitatively to the corresponding mercaptides.

Diphenyl sulphide is reduced by sodium in liquid ammonia to benzene, sodium sulphide and a small amount of water-insoluble gas. Phenyl *iso*thiocyanate with sodium in liquid ammonia yields aniline, sodium sulphide, no cyanide and a relatively small amount of biphenyl. A 71% yield of benzene, sodium sulphite and a small amount of biphenyl have been obtained by reducing sodium benzenesulphonate with sodium in liquid ammonia. Petroleum may be purified from organic sulphur contaminants by treatment with sodium in liquid ammonia.[1]

Ethylmercuric chloride reacts with sodium in liquid ammonia according to the equation: $C_2H_5HgCl + 3Na + NH_3 \rightarrow NaCl + NaHg + C_2H_6 + NaNH_2$.[38]

Trimethylboron ammine reacts as follows: $(CH_3)_3BNH_3 + Na \rightarrow (CH_3)_3BNH_2Na + 0{\cdot}5H_2$.[39] Tetramethylboronhydride, $(CH_3)_4B_2H_2$, is split equally into the ammine of dimethylboronhydride, $(CH_3)_2BH.NH_3$, and the disodium salt, $Na_2HB(CH_3)_2$.[40]

Sodium reacts with trimethylgallium in liquid ammonia: $2(CH_3)_3GaNH_3 + Na \rightarrow [(CH_3)_3Ga]_2NH_2Na + 0{\cdot}5H_2 + NH_3$ and $2(CH_3)_3GaNH_3 + 2Na \rightarrow [(CH_3)_3Ga]Na_2 + 2NH_3$. The first reaction is the chief one, 60–100% of the total gallium reacting in this way, whereas 30–0% reacts according to the second equation.

Under similar conditions dimethylgallium chloride is reduced to dimethylgallium which combines with ammonia and may be obtained as a solid at −33°C. It decomposes slowly at this temperature, more rapidly at room temperature, to the amide: $(CH_3)_2GaNH_3 \rightarrow (CH_3)_2GaNH_2 + 0{\cdot}5H_2$. With excess sodium in liquid ammonia the ammine of dimethylgallium reacts thus: $(CH_3)_2GaNH_3 + Na \rightarrow (CH_3)_2GaNH_2Na + 0{\cdot}5H_2$.[41] Ethyl-, methyl- and *iso*amylgermane with sodium in liquid ammonia yield germanyl salts but the reactions are not quantitative.[42]

Dimethylstannyl, diphenylstannyl and diphenylgermanyl react with sodium in liquid ammonia to form the corresponding disodium salt: $(CH_3)_2SnNa_2$, Ph_2SnNa_2 and Ph_2GeNa_2.[1]

Triphenylsilane reacts with sodium in liquid ammonia to give di(triphenylsilicon)imine, $[(C_6H_5)_3Si]_2NH$.[43]

Trimethylstannyltriphenylsilane is converted to the sodium derivatives $(C_6H_5)_3SiNa$ and $(CH_3)_3SnNa$ with sodium in liquid ammonia, and trimethylstannane and triphenylstannane to their sodium salts, $(CH_3)_3SnNa$ and $(C_6H_5)_3SnNa$. The latter is converted in part to the disodium salt, $(C_6H_5)_2SnNa_2$.[1]

Triethylgermane does not appear to react with sodium in liquid ammonia but the triphenyl derivative gives the monosodium salt with some disodium salt. Methyl- and *n*-propyl-triphenylgermanes are not attacked by sodium in liquid ammonia and no appreciable reaction occurs with tetraethylgermane. Tetraphenylgermane is converted to the sodium salt by the following slow reaction: $(C_6H_5)_4Ge + 2Na + NH_3 \rightarrow (C_6H_5)_3GeNa + C_6H_6 + NaNH_2$. With excess sodium the disodium salt, $(C_6H_5)_2GeNa_2$, is formed. Tetramethylstannane with sodium and liquid ammonia gives $(CH_3)_3SnNa$, $NaNH_2$ and CH_4; tetraphenylstannane behaves similarly but some of the sodium triphenylstannide is further substituted yielding the disodium salt.[1] Bis(trimethylstannyl)methane and bis(trimethylstannyl)ethylene react with sodium in liquid ammonia, the former according to the following equations: $CH_2[Sn(CH_3)_3]_2 + 2Na + NH_3 \rightarrow (CH_3)_3SnNa + (CH_3)_3SnCH_3 + NaNH_2$; $(CH_3)_3SnCH_3 + 2Na + NH_3 \rightarrow (CH_3)_3SnNa + CH_4 + NaNH_2$ and the latter according to the equations: $(CH_3)_3SnCH = CHSn(CH_3)_3 + 2Na + NH_3 \rightarrow (CH_3)_3SnNa + CH_2 = CHSn(CH_3)_3 + NaNH_2$; $CH_2 = CHSn(CH_3)_3 + 2Na + NH_3 \rightarrow CH_2 = CHSn(CH_3)_2Na + CH_4 + NaNH_2$.[1]

Triethyl-, tripropyl-, tributyl- and triamyl-silicyl fluorides do not react with sodium in liquid ammonia at its boiling point.[1] Sodium does not react with triethylgermanyl bromide in liquid ammonia but only with the ammonium bromide formed by ammonolysis: $2(C_2H_5)_3GeBr + 3NH_3 \rightarrow [(C_2H_5)_3Ge]_2NH + 2NH_4Br$; $2NH_4Br + 2Na \rightarrow 2NaBr + 2NH_3 + H_2$.[1]

Sodium triphenyl stannide is formed when triphenylstannyl bromide and iodide are treated with sodium in liquid ammonia. Trimethylstannyl bromide is reduced to sodium trimethyl stannide. An almost quantitative yield of hexamethylstannoethane is obtained if only one equivalent of sodium is used: $2(CH_3)_3SnBr + 2Na \rightarrow (CH_3)_3Sn{-}Sn(CH_3)_3 + 2NaBr$. Dimethylstannyl bromide is converted to the sodium salt.

The heats of reaction of trimethylstannyl bromide with sodium in liquid ammonia are as follows: $(CH_3)_3SnBr,NH_3am + Na \rightarrow (CH_3)_3Sn + NaBr\ am - 30{,}470$g.-cal.; $(CH_3)_3SnBrNH_3am + 2Na \rightarrow (CH_3)_3SnNa + NaBr\ am - 34{,}300$ g.-cal.; $(CH_3)_3SnBr + Na \rightarrow NaBr + (CH_3)_3Sn - 37{,}470$g.-cal.[1]

The free group, diphenyltin $(C_6H_5)_2Sn$, or the disodium salt $Na_2Sn(C_6H_5)_2$, is obtained by the action of sodium in liquid ammonia on diphenyltin dibromide or diiodide, depending upon the amount of sodium used. Dimethyltin dibromide is converted to the compounds, $(CH_3)_2Sn$, $(CH_3)_2SnNa_2$ or $NaSn(CH_3)_2Sn(CH_3)_2Na$, again depending upon the amount of sodium used in liquid ammonia solution.[1]

Other reactions of organohalides of tin and lead with sodium in liquid ammonia are tabulated by Watt.[1]

Triphenylgermanium oxide reacts with sodium in liquid ammonia to form sodium triphenylgermanide and triphenylgermanolate: $[(C_6H_5)_3Ge]_2O + 2Na \rightarrow (C_6H_5)_3GeNa + (C_6H_5)_3GeONa$. Trimethylstannyl phenoxide $(CH_3)_3SnOC_6H_5$ is converted to sodium phenoxide and either trimethylstannyl or sodium trimethylstannide depending upon the quantity of sodium used. Trimethylstannyl hydroxide reacts according to the equation: $(CH_3)_3SnOH + Na \rightarrow (CH_3)_3Sn + NaOH$. Trimethylstannylamine reacts with sodium in liquid ammonia as follows: $(CH_3)_3SnNH_2 + 2Na \rightarrow (CH_3)_3SnNa + NaNH_2$. Reactions of organometallic compounds of tin and lead with solutions of metals in liquid ammonia are tabulated by Watt and many references are given.[1]

Organo antimony compounds of the type $(C_6H_5)_2SbI$ react with sodium in liquid ammonia to form sodium salts, $(C_6H_5)_2SbNa$ and possibly $(C_6H_5)_2Sb$.[1] Organobismuth halides give highly reactive deep red coloured compounds of the type R_2BiNa in liquid ammonia solutions of sodium and although they decompose slowly they are sufficiently stable to react promptly with $R'X$ compounds (where X = halide) giving unsymmetrical organobismuth compounds, $R_2R'Bi$, and a water soluble type, $R_2BiC_6H_4COOH$.[44]

REACTIONS OF SODIUM WITH ORGANIC COMPOUNDS

Sodium organo compounds may be divided roughly into three main groups: those in which the metal is bonded to the carbon atom as in sodium methyl, $NaCH_3$, and sodium phenyl, NaC_6H_5, those in which the 'activity' of the C–H link is increased by attachment of doubly linked or aromatic radicals as in sodium benzyl, $NaCH_2C_6H_5$, and sodium triphenylmethyl, $Na(C_6H_5)_3CH$, and, lastly, derivatives of hydrocarbons containing acidic hydrogen, such as derivatives of acetylene and the monosubstituted acetylenes.

The first group are colourless salt-like compounds, insoluble in paraffin hydrocarbons and benzene, very reactive towards other organic compounds, extremely sensitive to air and moisture, spontaneously inflammable in air, and non-conducting in the fused state or in solvents other than dimethyl zinc.

The second group are highly coloured, usually orange or red, soluble in organic solvents, sensitive to air and moisture, generally spontaneously inflammable in air and electrically conducting in solution.

Members of the third group are salts. They are colourless and insoluble and are hydrolyzed by ionizing solvents such as water and alcohol. They are readily oxidized but are usually stable in air at ordinary temperatures.[1]

The thermal decomposition of sodium methyl is represented by the equation: $8NaCH_3 \rightarrow 6CH_4 + Na_2C_2 + 6Na$. The main reaction in the spontaneous decomposition of sodium ethyl at ordinary temperatures is: $2NaC_2H_5 \rightarrow Na_2C_2H_4 + C_2H_6$; at 90°–100°C., the products are sodium hydride and ethylene: $NaC_2H_5 \rightarrow NaH + C_2H_4$. Some ethane is also formed.[2]

Compounds of the type RNa react rapidly at or near room temperature with diphenylethylene, ketones, acid chlorides, ammonia, water and aqueous hydrochloric acid. The order of increasing 'reactivity' of the alkali metal compounds measured by Gilman and Young by (*a*) the reaction between benzonitrile and phenylacetenyl alkali metal compounds, (*b*) the metallation of dibenzofuran and ethylalkalimetal compounds and (*c*) the reactions of ketyls with *n*-butyl chloride, is RLi, RNa, RK, RRb, RCs. The reactivity is also influenced by the R group.[3]

Free hydrogen at room temperature decomposes the reactive organometallic compounds: $C_6H_5Na + H_2 \rightarrow C_6H_6 + NaH$; the speed of such reactions increases in the order, C_6H_5Li, C_6H_5Na, C_6H_5K, C_6H_5Rb, C_6H_5Cs.[4]

Organometallic compounds may be considered as salts derived from the weakly acidic RH compounds: $2RH + 2M \rightarrow 2RM + H_2$. The order of acidity is: $C_2H_6 < C_6H_6 < CH_3C_6H_5 < CH_2(C_6H_5)_2 < CH(C_6H_5)_3 <$ xanthen < aniline < fluorene < phenylacetylene < alcohols < phenol. Thus, sodium phenyl may be obtained from sodium ethyl, and sodium benzyl from sodium phenyl: $NaC_2H_5 + C_6H_6 \rightarrow NaC_6H_5 + C_2H_6$; $NaC_6H_5 + C_6H_5CH_3 \rightarrow NaCH_2C_6H_5 + C_6H_6$.[5] The stability of metal organo compounds has been studied by Jaffé and Doak[6] and the electrolytic nature of organo-alkali compounds by Ziegler *et al.*[7]

Sodium organo compounds are prepared by the action of sodium on mercury dialkyls or diaryls: $Hg(CH_3)_2 + 2Na \rightarrow 2NaCH_3 + Hg$. In order to exclude oxygen, moisture and carbon dioxide, these reactions were first carried out in sealed evacuated vessels but it has since been shown that the reactions may be carried out successfully in a stream of pure dry nitrogen. Schlenk and Holtz[8] have thus prepared sodium methyl, sodium ethyl, sodium propyl, sodium octyl, sodium phenyl and sodium benzyl. Sodium methyl is prepared in ligroin, b.p. about 80°C., sodium ethyl and propyl in a higher boiling ligroin, b.p. 100°–150°C., and sodium octyl, phenyl and benzyl in benzene. Sodium ethyl has been prepared by Gilman and Young by stirring 0·04g.-atoms of sodium in petroleum ether, b.p. 68°–77°C., with 0·01mole of mercury diethyl for one and a half days in a stream of pure dry nitrogen.[3] Sodium reacts with di-*sec.*-butylmercury in dodecane at 20°–25° in an atmosphere of nitrogen to give a reaction mixture which on subsequent treatment with carbon dioxide, followed by water, yields an aqueous layer from which the two acids, $CH_3(C_2H_5)CHCOOH$ and $CH_3(C_2H_5)C(COOH)_2$ may be isolated. At room temperature 0·07mole of sodium and 0·016mole of di-*sec.*-butylmercury stirred for eight days in an apparatus swept out with nitrogen yield gases which on passage over bromine give 0·013mole of butene as dibromobutane and 0·004–0·005moles of butane. No 3:4-dimethylhexane has been isolated from the residue.[9]

Sodium alkyls and aryls are also formed by the action of sodium in benzene on the corresponding organo halides.[10] Chlorides are more effective than bromides and bromides than iodides in the formation of alkali metal organo compounds.[11,12]

High surface sodium, adsorbed on inert solids and suspended in a non-reactive liquid, is used for the preparation of sodium alkyls and aryls. For example, sodium amyl is obtained by adding amyl chloride to high surface sodium adsorbed on zircon and suspended in petroleum ether at 0° to 10°C. Subsequent carbonation with solid carbon dioxide, followed by acidification with a mineral acid yields caproic acid which is extracted with ether or benzene.[13] Sodium amyl is also prepared using dispersed sodium. To prepare sodium dispersions clean, dry apparatus must be used; the sodium is melted in an inert medium which boils at a temperature above that of the m.p. of sodium; heptane, *n*-octane, toluene, xylene, naphtha, kerosene, mineral oil and *n*-butyl ether are suggested solvents. A small amount of dispersing agent such as aluminium laurate, octoate or stearate, calcium stearate, copper oleate, zinc stearate, cellulose nitrate or butadiene, 0·01 to 2% of the total weight of reactants, is added to the mixture which is vigorously agitated mechanically at 100°–110°C. The most efficient agitator is one which revolves at a high speed in the fluid mixture so that both sodium and the inert medium are drawn up into a cylinder and discharged through slots. The high tangential shear produced at the exterior surface of the cylinder as the mixture issues from the slots causes the reduction of the particle size of the sodium to the range of submicron to 20 microns in diameter. The use of a baffled vessel reduces swirl. The advantages of sodium dispersions in carrying out organic reactions are many. The particles react completely before a protective film is formed; reactions may often be completed in minutes instead of hours; violent surging of reactions may be avoided by adding the dispersion at a controlled rate; an increased yield is usually obtained, a lower reaction temperature is required and side-reactions are decreased. Reactions may be carried out over a wide range of temperature, -80°C. to 400°C., and more expensive reagents such as sodium alcoholates, sodium hydride, sodamide, triphenylmethyl sodium can in many cases be replaced by sodium in this form.[14]

Sodium and amyl chloride in *iso*propylbenzene at -6° to -11°C. on standing overnight yield, when subsequently carbonated and acidified, cumic acid with a smaller amount of the *o*-acid.[15]

Sodium amyl, prepared from sodium and amyl chloride at -10°C. by stirring at 5,000r.p.m. with *n*-heptane as solvent, when stirred at 10,000r.p.m. for a further 1·5hr., yields on carbonation with solid carbon dioxide about 85% of the sodium salt of caproic acid and some 3–7% of decane. Similar runs at 50°C. for 3hr. yield also about 4% of a water-soluble pentenedicarboxylic acid. When one equivalent of sodium *tert.*-amylalcoholate is added to the mixture before stirring and the mixture is heated at 50°C. for 3hr., subsequent carbonation yields 33% of sodium caproate, 11% of decane, 34% of the water-soluble pentenedicarboxylic acid and metallic sodium.[16]

Sodium amyl, sodium and anisole react, preferably in the presence of certain alkoxides, forming the amyl derivative, *o*-$C_5H_{11}C_6H_4OCH_3$. *o*-Cresol methyl ether may be alkylated similarly.[17]

When heated with sodium amyl and an alkoxide, benzene is dimetallated chiefly in the *meta* positions but the ratio of *meta* to *para* can be altered by the choice of alkoxide associated with the reagent. Thiophen is readily dimetallated in the 2:5 positions, *p-tert.*-butylphenol in the 2:6 positions and *iso*propylbenzene and *sec.*-butylbenzene in the 3:5 positions.[18]

Sodium and sodium amyl are used for the metallation and cleavage of ethers, principally alkylphenyl ethers; thus methyl phenyl ether yields the sodium derivatives, *o*-$NaC_6H_4OCH_3$, $NaOC_6H_5$ or *o*-$C_5H_{11}C_6H_4OCH_3$ according to the temperature at which the reaction is carried out. Other alkylphenyl ethers undergo metallation and cleavage in a similar manner but metallation is not always a prerequisite to cleavage. Methyl phenyl ether is attacked by sodium alone to give the sodium derivatives *o*-$NaC_6H_4OCH_3$ and $NaOC_6H_5$.[19]

Sodium and amyl chloride at 20°C. react to form decane and some disproportionation products. In the presence of toluene the decane is largely replaced by hexylbenzene. The intermediate sodium compounds, sodium amyl and sodium benzyl, are insoluble in the medium. The yield of hexylbenzene is increased by the addition of certain salts and alkoxides.[20]

Sodium amyl and *iso*butene in pentane react, yielding on carbonation and acidification β-methylvinylacetic acid and β-methylglutaric acid; propene under similar conditions yields vinylacetic acid. Other similar reactions have been described.[21]

*iso*Butyl bromide and sodium react together to give sodium *iso*butyl which on carbonation yields the sodium salt of *iso*valeric acid: $(CH_3)_2CHCH_2Br + 2Na \rightarrow (CH_3)_2CHCH_2Na + NaBr$; $(CH_3)_2CHCH_2Na + CO_2 \rightarrow (CH_3)_2CHCH_2\text{-}COONa$.[22]

Triphenylchloromethane reacts with sodium in ether and benzene to give a 96% yield of sodium triphenyl.[23] When sodium is allowed to stand with triphenylchloromethane in benzene or ether in the presence of benzophenone, the metal first combines with the ketone to form the metal ketyl which reacts with the halogen compound yielding triphenylmethyl, sodium chloride and benzophenone. A similar reaction occurs when the ketone is replaced by tetraphenylethylene. Monochloro- and monobromo-benzene and butyl chloride are also carriers of sodium. A sodium halyl complex is first formed: $C_6H_5Br + Na \rightarrow C_6H_5\text{--Br--Na--}$ which may then react with triphenylchloromethane: $(C_6H_5)_3CCl + C_6H_5\text{--Br--Na--} \rightarrow (C_6H_5)_3C + NaCl + C_6H_5Br$, or react with another complex of the same kind: $2C_6H_5\text{--Br--Na--} \rightarrow (C_6H_5)_2 + 2NaBr$ or react with an atom of sodium: $C_6H_5\text{--Br--Na--} + Na \rightarrow C_6H_5Na + NaBr$. If left to itself the metal halyl eventually forms the free radical, phenyl and sodium bromide: $C_6H_5\text{--Br--Na} \rightarrow C_6H_5 + NaBr$.[24]

High surface sodium adsorbed on an inert solid suspended in benzene reacts with monochlorobenzene at 20°–30°C. to form sodium phenyl. Subsequent carbonation and acidification with mineral acid yields benzoic acid.[13] Sodium phenyl is also prepared when suitable sodium dispersions are treated with monochlorobenzene.[14]

Benzyl chloride when treated with dispersed sodium reacts to form 87–90% of dibenzyl: $2C_6H_5CH_2Cl + 2Na \rightarrow C_6H_5CH_2CH_2C_6H_5 + 2NaCl$.[14]

Propyl chloride and sodium in xylene yield propane, propylene and hexane.[25]

Organo chlorides and sodium in benzene treated with carbon dioxide at 30 lb. pressure give the following yields of acids from the corresponding chlorides: 76% of p-$CH_3C_6H_4COOH$, 58% of m-$CH_3C_6H_4COOH$, 12% of p-$C_6H_5C_6H_4COOH$, 28% of p-$(CH_3)_2NC_6H_4COOH$, 45% of C_6H_5COOH. Tertiary carbinols are formed when the reaction is carried out in the presence of diethyl carbonate. For example, 0·1mole of the chloride, $C_6H_5C_6H_4Cl$, 0·42mole of diethyl carbonate and 0·22g. of sodium wire in 100ml. of benzene heated for 10hr. yield 23% of the pure tertiary carbinol, $(C_6H_5C_6H_4)_3COH$. Monochlorobenzene gives 66% of the carbinol $(C_6H_5)_3COH$. Numerous other similar condensations have been described. Caution is necessary in carrying out these reactions; if the reaction becomes uncontrolled it proceeds with explosive violence. Methods of removing the protective film which forms on the sodium surface are discussed.[26]

Sodium acts on 1:4-dibromo-2-butene in dry ether at room temperature to give 1:8-dibromo-2:6-octadiene which is then transformed into 1:6-octadiene, dodecatriene and unsaturated higher analogues. No products of composition other than a multiple of four carbon atoms are isolated nor are any cyclic products formed.[27]

A yellowish halogen-free polymer, $(C_6H_4)_4$, is obtained when a mixture of 2:3-dibromo-1:3-*cyclo*hexadiene and sodium in dry dioxan is kept for two days in a sealed tube.[28]

The reaction of 1:4-dibromo-2-*cyclo*hexene with sodium in boiling xylene yields 1:3-*cyclo*hexadiene. If the solvent is not heated, the product, 1:2-dibromo-3-*cyclo*hexene is formed.[29]

The compounds, dimethylvinylcarbinol, $CH_2{=}CHC(OH)(CH_3)_2$, acetylene and ethylene are obtained when vinyl bromide and acetone in ether are added dropwise for 10hr. to sodium sand in ether with cooling.

When the mixture formed by adding vinyl bromide and acetone in ether dropwise for 10hr. to sodium sand in ether with cooling is decomposed with ammonium chloride, extracted with ether and distilled, the products, 2-methyl-3-butene-2-ol, $CH_2{=}CHC(OH)(CH_3)_2$, acetylene and ethylene are obtained. Small amounts of mesityl oxide and pinacol and butadiene are also formed.[30]

A series of alcohols has been prepared by the reaction of organic chlorides with carbonyl compounds in the presence of finely divided sodium. Alcohols so prepared are: 2-benzyl-2-propanol, $(C_6H_5CH_2)_2CH(OH)CH_3$, $[(CH_3)_2CH]_2C(OH)CH_2C_6H_5$, 2:6-dimethyl-4-benzyl-4-heptanol, $C_6H_5CHCH(OH)C_2H_5$, $[(CH_3)_2CH]_2C(OH)C_6H_5$, $C_6H_5CH(OH)C_2H_5$, 6-methyl-6-undecanol, 2-methyl-4-

*iso*butyl-4-nonanol and 2:4-dimethyl-3-*iso*propyl-3-pentanol.[31]

When a mixture of carbon tetrachloride and sodium is subjected to shock by striking with a hammer the reaction is violently explosive; with chloroform a moderately strong reaction occurs. The alkali metals act as powerful detonators with organic halogen compounds and the order of the power of the explosion decreases from sodium–potassium alloy through potassium, sodium to lithium.[32,33]

On slightly warming a mixture of carbon tetrachloride with a 1% sodium amalgam, a brisk reaction occurs: $4Na + CCl_4 \rightarrow 4NaCl + C$.[34]

A summary of the work carried out by Polanyi and his collaborators up to 1942 on the atomic reactions of sodium with organic halides by the sodium 'flame' method has been given by Bawn,[35] who describes experimental procedures and theoretical considerations, with numerous references to the literature. A later review by Warhurst[36] is mainly concerned with developments up to 1951.

By measuring the reaction velocity of alkyl halides with sodium vapour by the diffusion flame method it has been shown that the reaction inertia decreases in the order; F, Cl, Br, I for the halides of a given radical; with increase in length of the carbon chain; with increase in the number of chlorine atoms and the more so the closer these are together, and with the introduction of carbonyl oxygen. The inertia also decreases in the order: primary, secondary, tertiary halides but is not affected by branching of the chain. The reaction is retarded by a double linking at the carbon atom to which the chloride is attached, but the inertia is reduced if the double linking occurs at the next carbon atom. A small reaction inertia appears to be associated with a large dipole moment.[37]

A few examples of reactions of sodium vapour in a highly diluted state with organic halides are given below.

A rapid gas reaction occurs and free radicals are formed when nitrogen at a few mm. pressure is passed with sodium vapour at 10^{-3}mm. and at about 270°C. into a space filled with an alkyl halide. The presence of free radicals is substantiated by the induced chlorination of methane. A sodium-loaded methane stream is passed into methyl bromide and at a point where all the sodium is used up, the gas stream containing the free radicals and methane is allowed to react with chlorine: $Na + CH_4 + CH_3Br \rightarrow NaBr + CH_3 + CH_4$; $CH_3 + Cl_2 \rightarrow CH_3Cl + Cl$; $Cl + CH_4 \rightarrow CH_3 + HCl$. The resulting chlorination of methane is 0·1 to 0·5 the intensity of that by direct use of sodium, methane and chlorine: $Na + Cl_2 \rightarrow NaCl + Cl$; $Cl + CH_4 \rightarrow CH_3 + HCl$; $CH_3 + Cl_2 \rightarrow CH_3Cl + Cl$. By substituting iodine for chlorine and using methyl bromide or ethyl bromide, and cooling the products in cold traps, methyl iodide or ethyl iodide may be isolated in yields of 10% for a sodium pressure of 5×10^{-4}mm. and 2% for a pressure of 10^{-2}mm. The yield increases with increase in rate of flow.[38] The free radicals react with hydrogen at 300°–500°C. to give methane: $CH_3 + H_2 \rightarrow CH_4 + H$. In the absence of hydrogen the free radicals are dimerized: $2CH_3 \rightarrow C_2H_6$.[39]

Whereas the principal product in the reaction of sodium vapour with methyl iodide is ethane, some methane, ethylene and hydrogen are also formed. With ethyl iodide the main product is butane with smaller amounts of ethane, ethylene, methane and hydrogen. Some propane is also present and is considered to be a pyrolysis product of butane. It is concluded that at low temperatures the dominant reaction for both methyl and ethyl radicals is a combination of the two to form a saturated hydrocarbon. At higher temperatures disproportionation and reaction with other molecules occur.[40]

Sodium vapour in a highly diluted state reacts with monochlorobenzene to give a 90% yield of diphenyl. Dibenzyl is obtained from benzyl chloride.

The cyanogen radical is formed from cyanogen chloride or cyanogen.[41] The vinyl radical, set free when sodium vapour reacts with vinyl chloride or bromide, reacts with hydrogen to form ethylene. Disproportionation of the vinyl radical leads to the formation of acetylene and ethylene.[42]

Little or no luminescence is observed when monohalogen organic compounds react with sodium in the highly diluted state, but an intense luminescence of the *D*-line of sodium is produced when the number of halogen atoms is increased. All the saturated dihalides so far examined show this characteristic luminescence. $RX_2 + Na \rightarrow NaX + -RX$; $-RX + Na \rightarrow NaX + R$. The excitation reaction is the exothermal rearrangement of the reaction product R, whereby an unsaturated molecule may be formed either by the closure of a double bond or migration of a hydrogen atom: $CH_2BrCH_2 + Na \rightarrow NaBr + CH_2 = CH_2$; $-CH_3CHBr + Na \rightarrow NaBr + CH_2 = CH_2$; or a cyclic molecule may be produced; $-CH_2BrCH_2CH_2 + Na \quad NaBr + \underbrace{CH_2-CH_2-CH_2}$. The internal energy carried by the sodium halide is transferred to a sodium atom by collision, thus producing luminescence.[35]

The primary reaction of sodium vapour with trifluoromethyl iodide, bromide and chloride is shown by the diffusion flame method to be: $CF_3I + Na \rightarrow NaI + CF_3$. The activation energies for the iodide, bromide and chloride are 1·7, 2·3 and 7·0kg.-cal. per mole respectively. The free CF_3 radicals combine to give hexafluoroethane, C_2F_6, but if hydrogen is used as the carrier gas trifluoromethane is formed: $CF_3 + H_2 \rightarrow CHF_3 + H$. The simultaneous formation of tetrafluoroethylene is due to the decomposition of CF_3 radicals. Carbon tetrafluoride does not react with sodium under the conditions of the sodium flame reaction.[43] The kinetics of the diffusion flame reaction between sodium vapour and some fluorinated methyl halides are described by Reed.[44]

The theory of diffusion flames is discussed by Cvetanovic and Le Roy with particular reference to the reaction of sodium atoms with ethyl chloride.[45]

The steric factor and activation energy of the reaction: $Na + C_2H_5Cl \rightarrow NaCl + C_2H_5$ has been studied over the range of 260°–380°C. by the diffusion flame method. The activation energy is 10·2kg.-cal. per mole ± 0·5kg.-cal. The steric factor is 1·0 ± 0·3 based on the customary value assigned to the collision diameter.[46] The inductive effect and chemical reactivity with respect to reactions of halides with sodium atoms has been studied by Smith and Eyring. Attempts are made to explain differences in activation energy for similar reactions of a homologous series by calculations of charge distribution.[47,48]

Meer and Polanyi have made a comparison of sodium vapour reactions with other chemical reactions.[49]

Hartel and Polanyi[39] give the following values for the heats of activation in reactions of halogen alkyls with atomic sodium: $Na + RX = NaX + R$ where R is the alkyl and X the halide radical. The values expressed as kg.-cal. are: $CH_3F > 25$; CH_3Cl, 8·8; CH_3Br, 3·2; CH_3I, 0; CH_2Cl_2, 5·0; $CHCl_3$, 2·0; CCl_4, 0; C_2H_5Cl, 7·3; C_2H_5Br, 4·4; C_2H_5I, 1·7. Activation energies expressed as kg.-cal. for reactions of organic halides with sodium atoms have been given by Gieb:[50] CH_3I, C_6H_5I, $C_6H_5CH_2Cl$, C_6H_5COCl, CH_3COCH_2Cl, 0; CCl_4, 1; C_2H_5I, 1·7; CH_3COBr, CH_3COCl, CNCl, 2·0; *n*-C_3H_7I, CH_3Br, C_6H_5Br, $CHCl_3$, 3·0; C_2H_5Br, $CH_2 = CHCH_2Cl$, $CH_3CH_2CHCl_2$, 4; $C_2H_5(CH_3)_2$-CCl, CH_3CHCl_2, 5; $(CH_2Cl)_2$, CH_2Cl_2, 5·2; $(CH_3)_3CCl$, $C_2H_5CH_2CHCl$, 5·5; CHCl = CHCl *cis* and *trans*, *n*-$C_5H_{11}Cl$, $C_5H_{11}Cl$(l *iso*) 6; $(CH_3)_2CHCl$, *n*-C_4H_9Cl, *iso*-C_4H_9Cl, 6·5; $CH_2 = CClCH_3$, *n*-C_3H_7Cl, 7; C_2H_5Cl, C_6H_5Cl, 7·5; $CH_2 = CHCl$, CH_3Cl, 9; $CH_3 > 25$.

The experimental results of Hartel, Meer and Polanyi[37] for the rates of reaction in the gaseous phase of $RCl + Na \rightarrow NaCl + R$ where R is CH_3, C_2H_5, *n*-C_3H_7, *iso*-C_3H_7, *tert.*-C_4H_9 have been shown by Taft[51] to fit the equation:

$\log K/K_0$ (or K/K_0) = $\sigma^*\rho^*$ where σ^* is a polar substituent constant for the group R relative to the standard methyl group and ρ^* is a constant giving the susceptibility of a given reaction series to polar substituents. A value of $\rho^* = 2{\cdot}480 \pm 0{\cdot}174$, probable error 0·05, is given for the vapour phase reactions of alkyl chlorides with sodium.

When vinyl iodide is allowed to react with sodium vapour in the 'diffusion flame', the predominant gaseous products are ethylene, acetylene and butadiene. It is considered likely that these compounds are formed by disproportionation and recombination of vinyl radicals. In the presence of hydrogen, ethylene is also formed: $C_2H_3 + H_2 \rightarrow C_2H_4 + H$. More vinyl iodide than sodium is used up in the reaction and a non-volatile organic iodide is formed; this has an important bearing on the calculation of the rate constant of the primary process.[52]

The action of organo metallic compounds on optically active halides tends to produce racemization as the carbon-halogen bond ionizes and the carbon-metal bond resists ionization. Lane and Ulrich[53] have carried out the Wurtz synthesis with optically active halides; their results support Morton's mechanism[54] rather than that involving free radicals.

Addition of sodium to double linkages may take place by a simple 1:2-addition: $(C_6H_5)_2C{=}C(C_6H_5)_2 + 2Na \rightarrow (C_6H_5)_2CNa.CNa(C_6H_5)_2$ or by a dimerizing addition: $(C_6H_5)_2C{=}CH_2 + 2Na + H_2C{=}C(C_6H_5)_2 \rightarrow (C_6H_5)_2CNaCH_2CH_2CNa(C_6H_5)_2$. Although tetraphenylethylene adds sodium, it does not add bromine, lithium or potassium. Sodium–potassium alloy, however, gives the dipotassium addition product probably through the intermediate formation of the sodium compound.[55]

The styrenes, $C_6H_5CH{=}C(CH_3)_2$, $C_6H_5CCH_3{=}C(CH_3)_2$, $(C_6H_5)_2C{=}CHCH_3$, $(C_6H_5)_2C{=}C(CH_3)_2$,[56] do not add sodium. Sodium does not combine with the following compounds: $(p\text{-}CH_3C_6H_4)_2C{=}C(CH_3)_2$, $(C_6H_5)_2C{=}CHC_2H_5$, $(C_6H_5)_2C{=}CHC_3H_7$ or $(C_6H_5)_2C{=}CHC_4H_9$.[57]

Reaction of sodium in ether with α-methylstilbene is rapid and a dark brown addition product is formed which reacts with alcohol to give α-methyldibenzyl. Anisal fluorene and sodium give a bright orange-red addition product which is decomposed by alcohol to 1:4-diphenylene-2:3-dianisylbutane. Sodium, fluorene and α-naphthaldehyde give α-naphthylidene fluorene and some 1-biphenylene-4-naphthyl-1:3-butadiene which is coloured deep yellow. The fluorene compound with sodium in ether gives an indigo-blue product decomposed by alcohol to 9-α-naphthomethylfluorene.[57]

Olefines such as styrene, 1-phenylbutadiene, butadiene and isoprene are polymerized by sodium powder, the last two compounds giving sodium rubbers. A small amount of sodium can convert many olefine molecules to large molecules or polymers: $RCH = CH_2 + R^1Na \rightarrow RCHNaCH_2R^1$; $RCH = CH_2 + RCHNaCH_2R^1 \rightarrow RCHNaCH_2CHRCH_2R^1$ and so on.[58]

The addition of 0·01 to 0·5 parts of 1:2-butadiene per 100 parts of monomeric material improves the pressing characteristics of synthetic rubbers obtained by the catalytic polymerization of monomers with finely divided sodium.[59] In the polymerization of butadiene with sodium catalyst, addition of a small amount of a hydroxy ether produces a product resembling natural rubber in processing characteristics.[60-63]

The action of sodium on piperylene, triphenylmethane and fluorene has been described.[64]

The mechanism of the addition of sodium to double linkings has been discussed by Schlenk and Bergmann[65] and the kinetics of polycondensations of compounds, such as 1:3-butadiene, $CH_2 = CHCH = CH_2$, with sodium studied by Bauer and Magat.[66]

A variety of uses for metallic sodium in the plastic industry for the manufacture of monomers, polymers, plasticizers and stabilizers are described by Sittig.[67]

Whereas the alkali metals alone do not catalyze the polymerization of ethylene, propylene or their mixtures, the catalytic effect of the oxides of chromium, molybdenum, tungsten or uranium is promoted by the addition of the alkali metals. In the examples given, sodium is used as the promoter.[68]

The polymerization of bivinyl by means of thin layers of sodium is complete in two hours at room temperature when the sodium layer is formed by condensation at −180°C., after 25hr. when the sodium layer is formed at −68°C., and after 48hr. at a sodium condensation temperature at 0°C. The crystallization effects of sodium at these temperatures accounts for the activity changes.[69]

Acetylides are formed by the action of acetylene on heated sodium or on a solution of the metal in liquid ammonia (see page 522).

Monoalkylacetylenes and sodium form similar metal derivatives such as $CH_3C \equiv CNa$.[3]

Phenylacetylene and sodium stirred in ether under pure dry nitrogen react at room temperature and on carbonation give a 74% yield of phenylpropiolic acid.[3]

Fluorene and high surface sodium, adsorbed on an inert solid suspended in an inert medium, yield sodium fluorenyl.[13]

Dibenzofuran reacts with sodium ethyl to give a disodium derivative, whereas lithium ethyl yields only a monolithium derivative.[55]

Alkali metals add to naphthacene or 1:2:3:4-tetrahydronaphthacene in nitrogen in the presence of ether or glycol dimethyl ether, yielding heteropolar complexes which contain ethers.[70,71]

Sodium reacts with a solution of naphthalene in 1:2-dimethoxymethane to produce a dark green solution which contains a compound of empirical formula $C_{10}H_8Na_2$. The solution reduces iron, nickel or cobalt chlorides to a finely divided metallic powder.[72]

Mixed catalysts, composed of sodium and a nitrogen-containing heterocyclic compound, are used for the condensation of aromatic compounds with unsaturated compounds. The products are useful intermediates in the preparation of detergents, insecticides, dyes and medicinals.[73]

Monosodium buccocamphor heated at 240°C. yields 2:3-dihydroxycymene, tetrahydrocarvone, carvacrol and polyhydroxy compounds. No hydrogen is evolved.[74]

The iron catalyst used in the Fischer–Tropsch reaction for the synthesis of liquid fuels from carbon monoxide and hydrogen is improved by the presence of a small amount of less than 10% alkali metal promoter and about 2–10% of finely divided carbon particles.[75]

By treating lard at 55°–170°C. for 3–120min. in the presence of 0·15–1·0% of alkali metal catalyst, it is converted to a beta crystalline modification as opposed to the normal beta form for processed lard. In this way its appearance, keeping and baking properties are improved.[76]

Sodium reacts with alcohols to form alcoholates and hydrogen: $Na + CH_3OH \rightarrow NaOCH_3 + 0{\cdot}5H_2$. The greater the number of carbon atoms in the molecule, the less rapid is the reaction; the rate of reaction also decreases from primary to secondary to tertiary alcohols.

The rates of reaction of sodium with ethyl alcohol and ethyl alcohol–water mixtures have been studied by Schnurmann. The view has been expressed that when a metal dissolves in a medium in which a gas is evolved, the size of the gas bubble influences the access of the reactive component of the liquid to the metal surface, and the larger are the adhering gas bubbles the smaller is the rate of dissolution of the metal. The size of the bubble is controlled by the viscosity of the reacting liquid. The results obtained by Schnurmann show that the higher the viscosity of the medium the more rapid is the reaction. In Table LI the weight of sodium is approximately the same in each case but the viscosity of the medium is altered by adding water; in Table LII the weight of sodium has been varied; the addition of larger pieces of sodium causes a greater increase in viscosity than the addition of smaller ones.

TABLE LI. - RATE OF REACTION OF SODIUM IN ETHYL ALCOHOL-WATER MIXTURES

% C_2H_5OH in water	Time of dissolution sec.
Once distilled over CaO	123
95	85

TABLE LII. - RATE OF REACTION OF SODIUM IN ABSOLUTE ETHYL ALCOHOL

Wt. of Na mg.	Time of dissolution, T sec.	Specific time of dissolution, t
198	607	3·1
120	425	3·5
109	397	3·6
95	365	3·8
80	360	4·5
65	271	4·2

($t = T/$wt. of Na)

Sodium is found to dissolve more rapidly in alcohol at a lower temperature than at a higher one; the addition of urea also causes a more rapid reaction.[77] No reaction occurs when sodium is treated with alcohol below −48°C.

The velocity of solution of sodium in solutions of ethyl alcohol or methyl alcohol in benzene, toluene or xylene is not constant over the solution reaction but drops as the concentration of alcohol falls. The rate of solution is proportional to the concentration of the hydrogen ions. The temperature coefficient of the reactions and the accelerating effect of stirring indicate the diffusive nature of the process.[78,79]

Measurements have been reported for the current produced when sodium is dissolved in methyl or ethyl alcohol, for the electrolytic decomposition of the alkoxides, the ionic mobilities and the degree of dissociation of the compounds. All the values are similar to those for sodium ions in aqueous solution. Alcoholates appear to resemble metallic hydroxides rather than true organic compounds.[80]

The solvation of sodium ions in methyl and ethyl alcohols and in acetone and acetophenone, based on the apparent molecular volume, has been calculated from published data.[81]

An incident has been described in which sodium covered with sodium methoxide or butoxide, formed in the presence of toluene, exploded when thrown into water.[82]

The production of sodium methoxide on an industrial scale by reaction of sodium with excess of alcohol has been patented. Excess alcohol, including alcohol of crystallization, is distilled off in the presence of an organic solvent such as an aliphatic or aromatic hydrocarbon which is inert to the alkoxide.[83]

The use of sodium amalgam as a raw material in the industrial preparation of sodium methoxide has been discussed from the technical and economic viewpoint by Nicolai.[84]

Alkaline earth metals are separated from alkali metals by treatment with lower aliphatic alcohols which do not affect the alkaline earth metal.[85] Calcium is recovered from mixtures containing sodium by vigorous agitation in an inert hydrocarbon, to liberate the calcium and disperse the sodium as small particles throughout the medium at a temperature above the melting point of sodium. The resulting mixture is separated into fractions, one containing essentially sodium dispersed in the inert medium and the other containing most of the calcium. The latter fraction is treated with an excess of one of the lower aliphatic alcohols when the undissolved calcium separates from the reaction mixture.[86]

Ethyl alcohol is oxidized when sodium amalgam is agitated with oxygen at room temperature in the presence of alcohol; acetaldehyde is formed, partly in the resinified form because of the action of the alkali. It is also formed when the oxygen is under pressure.[87]

Sodium and absolute alcohol reduce ethyl benzoate mainly to hexahydrobenzoic acid, but a small amount of tetrahydrobenzyl alcohol is also formed. Benzyl alcohol is reduced to toluene, benzaldehyde to toluene and benzoic acid. Nitrobenzene is converted principally to aniline but a small amount of hydrazobenzene, $(C_6H_5NH)_2$, is also formed. Phenol, phenyl ethyl ether and aniline are not appreciably attacked.[88]

Sodium and absolute alcohol convert the hydrazone, oxime or semicarbazone of steroids with a 17-keto group to compounds with a semicyclic 17-double bond.[89]

Sodium and ROH compounds reduce β-substituted propionitriles to 3-alkoxypropylamines. The reaction is carried out with sodium sand in dry toluene.[90]

Sodium and industrial *iso*amyl alcohol containing 20% of the isomer of b.p. 128°C. and 80% of the isomer, b.p. 132°C., reduce glycerides to fatty alcohols. An azeotrope of 8% water and 92% alcohol is distilled off before adding the sodium.[91]

Sodium and butyl alcohol in xylene reduce vegetable oils such as Babassu oil and Ucuhuba fat to aliphatic alcohols.[92]

*cyclo*Hexanone with *iso*amyl nitrite in the presence of sodium gives a red nitroso compound; the *iso*amyl alcohol liberated reacts with sodium and the nitroso compound is reduced to 2-hydroxy*cyclo*hexanone oxime.[93]

The use of sodium in the preparation of 6-(*N*-methyl-*p*-tolylsulphonamido)-quinoline has been described.[94]

The synthesis of 2-ethylhexanol by condensation of butanol with sodium, using aluminium, zinc, copper, magnesium, etc., as co-catalysts, at 250°-310°C. in an autoclave is described by Kobayashi *et al.* The products of reaction are 2-ethylhexanol, butyric acid, a C_{12} alcohol, a C_8 fatty acid and esters. Aluminium is the most favourable co-catalyst to improve the yield of 2-ethylhexanol, while copper appears to accelerate the formation of higher molecular weight products.[95]

The metallation of sodium phenoxide has been studied by Morton and Letsinger;[96] carbonation affords *o*-hydroxybenzoic acid, 2-hydroxy*iso*phthalic acid and hydroxyterephthalic acid.

The reduction of acids by sodium at high pressures to form fatty alcohols for use in the detergent industry has been described by Kulkarni.[97]

Terephthalic acid is reduced by pure sodium amalgam in the cold to the Δ^2-tetrahydro acid which is easily further reduced to the hexahydro acid. With ordinary sodium amalgam only the $\Delta^{2,5}$-dihydro acid is formed. This acid is not further reduced until it has been rearranged into the $\Delta^{1,5}$- and $\Delta^{1,4}$-acids. This behaviour of sodium amalgam according to Willstätter *et al.* indicates that the reduction of an organic compound consists in the addition of sodium at the position of partial affinity of the molecule, and the replacement of the sodium atoms by hydrogen under the influence of water. According to the above authors, pure sodium amalgam does not evolve hydrogen on treatment with water. Impurities in the sodium amalgam catalytically accelerate the decomposition of sodium amalgam by water with liberation of hydrogen which competes with the addition of sodium atoms to the unsaturated groupings. The influence of the pH on the course of the reduction with sodium amalgam has been studied. The effect of the addition of 0·001 part of various metals to sodium amalgam is to accelerate the decomposition of water: copper and silver relatively little, magnesium and zinc more, aluminium still more, tin and especially lead most. Comparative experiments show that sodium amalgam prepared in iron crucibles decomposes water 30–50 times faster than electrolytic amalgam.[98]

When the unsaturated acid $C_6H_5CH{=}C(COOH)CH{=}CH_2$ is reduced in carbon dioxide with sodium amalgam, the compound $C_6H_5CH_2C(COOH){=}CHCH_3$ is obtained.[99]

Sodium dispersions are used to induce complete and rapid reaction of sodium with ethyl acetate; practically quantitative yields of acetoacetic ester, based on sodium, are obtained.[14,100] Sodium acetoacetic ester has also been prepared by the action of high surface sodium, adsorbed on an inert solid suspended in an inert medium, on ethyl acetate.[13]

Sodium reacts with ethyl trifluoroacetate and ethyl trifluoroacetodifluoroacetate, $CF_3COCF_2COOC_2H_5$, the former giving ethyl $\gamma{:}\gamma{:}\gamma$-trifluoroacetoacetate, and the latter ethyl trifluoroacetodifluoroacetate.[101]

Sodium reacts with the fatty acid ester, $(C_6H_5CH_2)_2CHCOOC_2H_5$ to give a 78–83% yield of tetrabenzylacetoin, together with a trace of the diketone.[102]

The triacetate and tribenzoate of phloroacetophenone and the diacetates and dibenzoates of quinacetophenone, resopropiophenone and resobutyrophenone in the presence of sodium in dry toluene are subjected to molecular rearrangement. The acetates give chromone derivatives, the benzoates, flavone derivatives except in the case of the compound, 2:4-$(C_6H_5COO)_2C_6H_3$-COC_3H_7 which gives benzoic acid.[103]

Ethyl *o*-benzoylbenzoate on treatment with sodium yields a deep scarlet solution which on concentration gives 3-phenylphthalide, some neutral polymeric material and a large acid fraction. The reduction of trimethylacetic acid derivatives has also been described.[104]

The reduction and condensation of aliphatic esters with acetophenone and sodium in an anhydrous medium have been studied by Wiemann, Mamlok and Sobolewski.[105]

Sodium is used as a catalyst in the reaction between cyanuric esters of the type $\underline{N{=}C(OR)N{=}C(OR)N{=}C}(OR)$ (where R is a univalent radical of a primary ethylenically unsaturated monohydric alcohol containing 3 to 10 carbon atoms) and polyhydric alcohols containing primary and secondary –OH groups, such as in glycerol and ethylene glycol, to give resinous products which may be used as coating and moulding compositions.[106]

Acetone or mesityl oxide and sodium react at the metal surface and if the metal is introduced all at once in a finely divided form the high surface area promotes interaction of the molecules attached to the surface and as much as 40% of polymeric product is formed. If, however, the metal is added progressively, negligible quantities of polymer are produced.[107]

The reduction of saturated ketones with sodium yields a mixture of glycols and alcohols. The rate of reduction is decreased and the yield of alcohol increased, the greater is the amount of alkyl substitution on the carbon atom adjacent to the carbonyl. It is suggested that the reduction in these reactions involves a surface phenomenon and is therefore affected by steric variations.[108]

o-Acetoxyacetoarones undergo molecular rearrangement on treatment with sodium, forming *o*-hydroxyaroyl acetones.[109] The action of sodium on aliphatic ketones in an inert medium is discussed by Drweski and Wiemann.[110]

The mechanism of the reduction of aromatic ketones by sodium amalgam and alcohol has been studied by Bachmann. The reduction of ketones to hydrols proceeds through the intermediate formation of ketyl radicals.[111] Pinacols are reduced quantitatively to hydrols by sodium amalgam in anhydrous ether-benzene. This reaction also takes place through the intermediate formation of free ketyl radicals.[112]

The industrial preparation of hydroquinone by the reduction of quinone with sodium amalgam and water is discussed by Nicolai.[84]

The reactions between sodium and aliphatic, aromatic and mixed ethers have been studied by Durand. Diethyl ether reacts slowly forming sodium ethoxide and hydrogen; di-*iso*amyl ether reacts slowly in the cold and vigorously at the boiling point at which the metal is liquid; anisole, phenetole and veratrole react rapidly when hot until the reaction mass solidifies. Benzoyl ethyl ether behaves similarly.[113]

Sodium reacts with mercaptans to form mercaptides: $Na + RSH \rightarrow NaSR + 0{\cdot}5H_2$.[114]

The reaction between mononitriles and monoacetylenes to give substituted pyrimidines and pyridines is brought about by the presence of catalytic quantities of sodium.[115]

Aromatic nitro compounds in the form of an emulsion in an aqueous reagent are reduced by sodium amalgam; high concentrations of nitro compounds give azo and hydrazo compounds, whereas low concentrations favour amine formation.[116] The reduction of aromatic nitro compounds or azo derivatives with sodium amalgam may be carried out in the presence of an aqueous reagent which reacts with the amalgam, and a stable, water-miscible solvent for the organic compound which separates readily from the aqueous caustic alkali solution produced.[117] The technical and economic aspects of the industrial preparation of hydrazobenzene by reduction of nitrobenzene with sodium amalgam have been discussed by Nicolai.[84] A process for the reduction of nitrobenzene to hydrazobenzene by treatment in aqueous alcoholic solution with sodium amalgam in the presence of carbon is described by Hallie.[118]

Aniline added in theoretical amounts to high surface sodium deposited on activated carbon and heated at 180°C. yields sodium anilide which reacts with alkyl halides to give alkylanilines.[13]

Sodium forms an additive compound with pyridine to which the structure $Na \ldots NC_5H_5 \ldots C_5H_5N \ldots Na$ has been assigned.[119]

Two compounds, $(C_5H_5N)_2Na$ and $(C_5H_5N)Na$, are formed when pyridine is treated with dispersed sodium in the presence of certain oxygenated solvents such as 1:2-dimethoxyethane and tetrahydrofuran.[120]

Aliphatic N,N-dialkylamides are not affected by sodium in boiling benzene but N,N-dialkylbenzamides react readily.[104]

Whereas 1-alkyl-3-chloropiperidines are dehalogenated by sodium, acyclic β-chlorotertiary amines are not only dehalogenated but also decomposed to amines and olefines.[121]

The behaviour of certain indicators with sodium organo-compounds has been discussed. Sodium in pentane reacts with the compound $(CH_2{=}CHCH_2)_2O$ to form $CH_2{=}CHCH_2Na$.[122]

Cellulosic materials such as starches and dextrins on treatment with an alcoholic solution of an alkali metal at 80°–115°C. are converted to a 2-monoalkali glucopyranose polymer which reacts with an alkyl halide to form an ether in which the organic group is attached to the carbon next to the carbonyl group. The monoalkali glucopyranose polymer on treatment with a metal or other inorganic salt yields a 2-mono-inorganic glucopyranose polymer.[123]

Hydrogenation of galactose to dulcitol with sodium amalgam is accelerated by addition of lead.[124,125]

The reaction between dialkyl phosphoric acid halides and sodium has been studied by Baudler; the chloride, $(C_2H_5O)_2POCl$, gives $(C_2H_5O)_2OPP(O)(OC_2H_5)_2$ and $(C_2H_5O)_2(O)POP(O)(OC_2H_5)_2$. The compounds $(CH_3O)_2POCl$ and $(C_3H_7O)_2POCl$ and the bromides and iodides behave similarly.[126]

Coloured oily products useful as insecticides and systemic aphicides have been prepared by stirring compounds such as $[(CH_3)_2N]POCl$ and $(CH_3)_2N$-$[CH_3$-$(iso C_5H_{11})N]$-$POBr$ with sodium in toluene at 90° to 95°C.[127]

Phenoxychlorosilicanes, when heated with excess of sodium in boiling xylene, are slowly attacked and a dark bluish-black deposit is formed; the whole of the chloride ion is finally eliminated as sodium chloride, and the filtered solution contains the compound, $Si(OC_6H_5)_4$.[128]

Dichlorides, such as R_2SiCl_2, when heated with sodium yield open or closed-chain structures consisting of $-SiR_2-SiR_2-$ groups; no complex of the type :Si:C: is formed. At about 180°C. in the absence of a solvent, the compound $C_6H_5SiCl_3$ and sodium react slowly but almost quantitatively to give a grayish insoluble powder containing 25·1–26·8%Si; the product does not react with iodine or bromine and is not attacked by piperidine and aqueous alkalies. In boiling benzene or toluene the action of sodium is inappreciable. In boiling naphthalene the reaction with sodium is exothermic and goes to completion more rapidly than in the absence of a solvent. The main product has not been identified but all fractions of it from various solvents contain oxygen; some contain $Si(C_6H_5)_2$ groups and possibly $C_{10}H_7$ radicals. The compound, $C_6H_5SiCl_3$ in boiling benzene or xylene in a sealed tube at 150°C. is fairly readily attacked at first by sodium but prolonged heating is necessary to bring the reaction to completion. The crude product seems to be a mixture of compounds containing from about 6 to at least 50 silicon atoms in their molecules. The components contain not only SiC_6H_5 and $Si(C_6H_5)_2$ groups but also silicon atoms uncombined with carbon; some of the silicon atoms appear to be unsaturated, probably they are tervalent, but most of them become saturated by combination with oxygen.[129]

The following organosilicon compounds have been obtained by the reaction of XCH_2SiRY_2 and $R_3Si(CH_2SiR_2)_xY$ in the presence of sodium, where X is halogen and Y alkoxy or halogen and x is 0 or 1: $(CH_3)_3SiCH_2SiCH_3(OC_2H_5)_2$; $C_6H_5(CH_3)_2SiCH_2SiCH_3(OC_2H_5)_2$; $(CH_3)_3SiCH_2SiCH_3Cl_2$; $(CH_3)_3SiCH_2Si(CH_3)_2$-$CH_2SiCH_3(OC_2H_5)_2$; $(CH_3)_3SiCH_2SiCH_3(OC_2H_5)Cl$. These compounds may be used for the production of other organosilicon compounds.[130]

Hexaphenyldisilane, $(C_6H_5)_3Si$-$Si(C_6H_5)_3$, reacts with sodium in ethylene glycol dimethyl ether to give the sodium derivative, $(C_6H_5)_3SiNa$.[131]

Reactions of sodium with organosilanes at elevated temperatures have been studied by Benkeser and Foster.[132]

Sodium is used for the preparation of butyl tin compounds by a Wurtz reaction.[133] The fungicidal properties of organotin compounds have been described.[134]

Sodium in a highly active state is prepared by passing dry ammonia into a suspension of sodium in toluene (cooled by solid carbon dioxide–ether mixture) until all the sodium is dissolved and then allowing the ammonia to evaporate slowly while the mixture is being vigorously stirred. Powdered sodium produced in this way has been used to synthesize many-membered cyclic oxides and oxidoketones.[135]

Sodium passivated by excessive purity retards organic substitution reactions but the metal may be reactivated by alloying with copper, silver, lead or tin. These metals are converted to amalgams and then alloyed with sodium. The added copper is 0·00002–0·5% of the calculated weight of sodium while the required amounts of silver, lead or tin are double that of copper. Sodium reactivated in this way has been used for Würtz–Fittig reactions.[136]

The handling of sodium in organic reactions and techniques including the use of highly dispersed sodium; of soluble complexes of sodium with ammonia and with the compounds $(CH_3)_2O$–$C_{10}H_8$, $C_2(C_6H_5)_4$, $(C_6H_3)_3B$; of alloys of sodium with other metals and of primary derivatives of sodium, such as sodium hydride, sodamide, are described by Hansley. Applications in organic chemistry include reduction of aliphatic esters to alcohols, reduction of aliphatic nitriles to primary amines, simultaneous reduction and condensation of esters, refining of hydrocarbons, Claisen condensations such as the self-condensation of ethyl acetate to the ester $CH_3COCH_2COOC_2H_5$. Polymerization and condensation reactions of butadiene are described.[137]

Sodium reacts with triethanolamine to give the sodium derivative, $(C_2H_4OH)_2NC_2H_4ONa$.[138] Ethylphenylethanolamine with sodium yields the sodium derivative $C_2H_5N(C_6H_5)C_2H_4ONa$.[139]

SECTION XXVI

SODIUM ALLOYS

By MRS. F. DICKINSON

The high thermal conductivity, high specific heat and low density of the alkali metals are properties which make them particularly suitable for use as coolants in heat-transfer systems, for example the removal of heat from nuclear reactors. Liquid sodium and sodium-potassium alloys are now being used on a large scale for this purpose and as a result of this technological interest in the liquid alkali metals a considerable amount of new or revised data for the physical and chemical properties, the flow characteristics, the design of heat-transfer systems and their components, the effect of corrosion on materials of construction, the thermal stress and thermal stress fatigue and the safe-handling of non-radioactive and radioactive liquid metals and alloys as well as methods of fire protection has become available in the literature.[1] A report of the work on liquid metal technology from 1949 to 1954 is given by Werner[2] as has also a general account of sodium-potassium alloys.[3]

Sodium-potassium alloys have now become commercial products. Binary alloy systems of the alkali metals have been studied by Klemm[4] and Böhm and Klemm.[5] Thermal analysis and *X*-ray studies show that the compound Na_2K occurs in the sodium-potassium system. Sodium-potassium alloys, prepared by distillation of the metals, have been used by Rinck[6] to obtain freezing point diagrams. He states that there is an unstable combination, Na_2K, m.p. 6·6°C. and a eutectic melting at −12·5°C. containing 66 at.-% of potassium. A diagram of the liquidus curve from various data is shown in Fig. 1. where the eutectic mixture is seen to freeze at −12·3°C. .with 77·2% of potassium by weight.[1] Cryoscopic determinations of the molecular weight of potassium in sodium give a value of 46 which indicates the presence of 18% of diatomic molecules, K_2. The molecular weight of sodium in potassium by the same method is 35.[7] From a study of its crystal structure, the alloy, Na_2K is regarded as a "mixture" of potassium and sodium without special affinities between them. The forces in Na_2K must be about the same as in metallic potassium or sodium; the melting point of 7°C. for the alloy compared with that of potassium and sodium confirms this assumption.[8] An investigation of the sodium-potassium equilibrium diagram has also been made by MacDonald, Pearson and Towle[9] and by Kean[10] and the effect of pressure from 1 to 10,000kg./sq. cm. on the electrical resistance of the liquid phase examined. The rise in melting point with pressure is considerably less for the alloys than for the pure metals.

Henry and Raynor[11] in their work on the cohesion of alloys, show that where the two components of a binary alloy exhibit mutual solid solubility, the wider range of solution should be obtained where the smaller ion is dissolving in the solvent with the larger ion. Calculations made for alloys containing small ions bearing a high charge give good agreement with observed results for binary alkali metal systems; solid solution formation is restricted in all cases except potassium-rubidium, potassium-cæsium and rubidium-cæsium for which extensive ranges of solid solutions exist. The relative magnitudes of the liquidus depression in the system sodium-potassium is accounted for and the composition of the eutectic point interpreted.

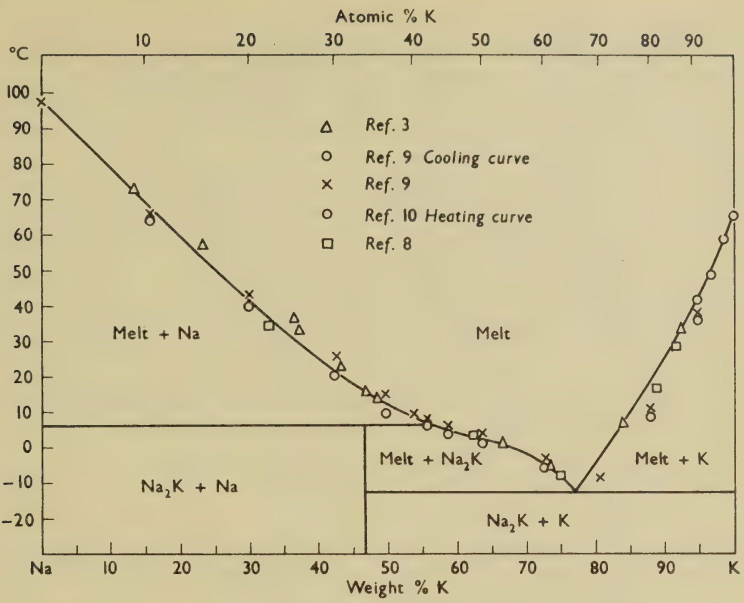

FIG. I. EQUILIBRIUM DIAGRAM Na–K

The following methods have been described for the preparation of sodium–potassium alloys. Freshly cut sodium and potassium are agitated under slightly wet ether.[12] Sodium is heated with potassium chloride above the fusion point of the halide: the salt layer becomes solid at ordinary temperature, while the alloy remains liquid.[13] Sodium vapour is passed in countercurrent through a molten potassium compound such as potassium hydroxide under vacuum and the resultant sodium and potassium vapours are condensed together.[14] Either sodium is heated with potassium hydroxide or potassium with sodium hydroxide and stirred in a well dried steel tube at the equilibrium temperature, 400°C., for 20–30 minutes. The system is rapidly chilled and two phases are obtained, one liquid sodium–potassium alloy (33 at.-% K) the other solid alkali hydroxides. The equilibrium constant for (Na) (KOH)/(K) (NaOH) = 0·5 at 400–700°C. The hydroxide phase contains 18·5% KOH and 81·5% NaOH. If slight carbonation occurs in the handling of the metals before carrying out the reaction, a secondary reaction which is of special importance to the main reaction, occurs:-[15]

$$2Na + K_2CO_3 \rightarrow 2K + Na_2CO_3$$

Clean liquid sodium–potassium alloy is obtained by floating the liquid alloy in a benzene–alcohol mixture and adding solid pieces of clean sodium and potassium until a bright globule of the desired size is obtained. The alloy may be stored under purified kerosene containing less than 0·5% of alcohol.[16] Sodium-potassium alloy is produced on a large scale by the reduction of potassium chloride with sodium at high temperature. Fractional distillation of the alloy may be used to obtain pure potassium.[17] Molten potassium chloride at 1550°F. is fed into the mid-point of a distillation column where it comes in contact with sodium vapour rising countercurrently. The product, a mixture of sodium and potassium vapours, is condensed to the alloy.[18]

Sodium and potassium alloys can be economically and almost quantitatively prepared by fusing sodium at 250–360° with an equivalent amount of caustic potash.[19] The reaction $2Na + KCl \rightleftharpoons Na/K + NaCl$ can also be carried out using potassium fluoride,[15,20] bromide[15,21] or iodide.[15,22] An alloy of sodium with 16·1% of potassium is in equilibrium with a fused salt containing 61·2% of potassium chloride, the remainder being sodium chloride. The mixture corresponds very nearly to the eutectic which melts at 650°C. An account of the equilibria between sodium and fused potassium hydroxide and halides has already been given (see page 478).

Jackson and Werner[23] give an example of the production of sodium-potassium alloy. Molten potassium chloride (1500°F.), 150lb., is charged into a preheated reaction vessel purged with nitrogen and 23lb. of brick sodium added to give a 2:1 mole ratio of potassium chloride to sodium. The reaction vessel and the condenser line are made of stainless steel, the rest of the system being of mild steel. Equilibrium is rapidly established and the more volatile metal phase distils giving a liquid metal distillate containing 47 at.-% of potassium.

The solubility of potassium in sodium is very nearly linear with temperature down to 7°C. and may be represented by the equation:-[1]

$$W = 57{\cdot}1 - 0{\cdot}586t$$

W = wt. %; t = degrees Centigrade.

The values given in Table I for the density of sodium-potassium alloys are taken from the Liquid Metals Handbook[1] which gives references to the sources from which the data have been obtained.

The specific volume of an alloy is obtained from the relation: $V = M(\text{K})V(\text{K}) + M(\text{Na})V(\text{Na})$ where $V(\text{K})$ and $V(\text{Na})$ are the specific volumes, i.e. the reciprocal of the densities, of potassium and sodium respectively, $M(\text{K})$ and $M(\text{Na})$ being the mole fractions of the elements designated. Table I gives both the experimentally determined values for two alloys and the calculated values, and the equation may be used to calculate the density of other alloys with equal accuracy.

TABLE I. DENSITIES OF TWO SODIUM-POTASSIUM ALLOYS

Temp. °C.	43·4% K by wt. Density g./cc.		78·6% K by wt. Density g./cc.	
	Exptl.	Calc.	Exptl.	Calc.
100	0·887	0·890	0·847	0·850
200	0·862	0·867	0·823	0·827
300	0·838	0·843	0·799	0·802
400	0·814	0·818	0·775	0·778
500	0·789	0·794	0·751	0·754
600	0·765	0·771	0·727	0·732
700	0·740	0·745	0·703	0·705

Ewing and Miller[24] prepared five alloys containing respectively, 93, 80, 66, 44 and 33% of potassium and measured their densities over a temperature range of 125°-694°C. For temperatures up to about 200°C. a glass dilatometer was used, but from 300°C. to 700°C. the buoyancy of a copper plunger suspended in the alloy was measured. Selected results are given in Table II.

Viscosity measurements on sodium–potassium alloys at 125°C. indicate the existence of the compound K_2Na in the liquid state by a maximum on the viscosity/composition curve at 77·2% of potassium. It is assumed that this compound is formed by the decomposition of the disodium compound Na_2K in the potassium-rich range since it does not exist as a solid.[25]

An Ostwald-type viscometer has been used to measure the viscosities of sodium–potassium alloys. The viscosity of an alloy containing 43·4 wt.-% of potassium at 72°C. was 1·267 relative to water at the same temperature. The values at higher temperatures have been calculated from the volumes of alloy flowing per second and the constant determined for the apparatus at 72°C. Measurements are first made on an alloy and water at the same temperature and under the same pressure head. If n_1, n_2, are the viscosities of the alloy and water respectively, d_1, and d_2 the densities, t_1 and t_2 the times required for equal volumes of the fluids to flow then: $n_1/n_2 = d_1t_1/d_2t_2$. From the relative viscosity X and the absolute viscosity of water at the same temperature, the absolute viscosity of the alloy is determined at that temperature. This value with the relation: $n = k/v$ gives a value for the constant k of the apparatus.[24,26] A closed-viscometer technique has been developed for reactive metals with unusually high surface-tension ranges. The values for the viscosity of several alloys from 60° or the m.p. to 200° have been measured and found to range uniformly between those for the pure metals. A 'mixture' equation has been applied to satisfy the data. It has also been shown that the temperature variation of the viscosity values can be adequately expressed by the equation given by Andrade,[27] $nv^{1/3} = Ae^{c/vT}$, where n is the viscosity, v the specific volume, T the absolute temperature and A and c constants for the given liquid.[28] A nickel viscometer of the Ostwald type has been used to substantiate measurements already made at 60° or the m.p. to 200° for sodium, potassium and several alloys to obtain further measurements up to 700°C. The results are given in Table III.[1,29]

TABLE III. VISCOSITY OF SODIUM-POTASSIUM ALLOYS

t °C.	Viscosity in Centipoises

Values for the empirical constants A and C in the equation $n = p^{1/3}Ae^{Cp/T}$ of three alloys are given in Table IV.

TABLE IV. EMPIRICAL CONSTANTS FOR ANDRADE'S FORMULA

Composition % K	Constants	
	$A \times 10^3$	C
0	1·42	739·8
28·3	1·046	743·3
43·3	1·052	722·3
69·9	1·059	694·0
100	0·9673	716·0

An ideal mixture law for viscosity is considered by Ishikawa[30] to be: $n = n_1 + (n_2 - n_1)\, KZm/(1 - Zm + KZm)$ where n_1, n_2, n denote the viscosities of components 1, 2, and the mixture respectively, Zm the mole fraction of component 2, K a constant which depends on the mutual attraction of the components. The extraordinary values of K in the sodium–potassium system suggest compound formation.

Values for the surface tension of sodium–potassium alloys,[1] obtained from unpublished data from the U.S. Naval Research Laboratory, are given in Table V.

Ewing and Miller[24] report the vapour-liquid equilibria for mixtures of sodium and potassium determined in an apparatus of 18-8 stainless steel. The results obtained are given in Table VI.

TABLE V. SURFACE TENSION OF SODIUM-POTASSIUM ALLOYS

The changes in enthalpy of potassium and three potassium-sodium alloys have been measured at temperatures from 0° to 800°C. with an ice calorimeter.[31] The heat capacities have been derived from enthalpy values, and an empirical equation given to fit the data. For an alloy containing 78·26% of potassium the heat capacity, Cs, in absolute joules per g.°C. at t° is given by the expression: $Cs = 0{\cdot}93860 - 2{\cdot}1924(10^{-4})t + 2{\cdot}1091(10^{-7})t^2 + 0{\cdot}05636(1 - 0{\cdot}0040549t)e^{-0{\cdot}0040549t}$ over the temperature range 0° - 800°C. For an alloy containing 53·64% of potassium $Cs = 1{\cdot}13625 - 5{\cdot}1798(10^{-4})t + 4{\cdot}6266(10^{-7})t^2$ over the temperature range 50° - 800°C. For an alloy containing 44·8% of potassium $Cs = 1{\cdot}16587 - 4{\cdot}3818(10^{-4})t + 3{\cdot}7974(10^{-7})t^2$ over the temperature range 50° - 800°C.

These equations have been used to calculate the heat capacities at the temperatures shown in Table VII.

TABLE VII. HEAT CAPACITIES OF SODIUM-POTASSIUM ALLOYS

Temperature °C.	Heat Capacity Absolute Joules per g.°C. at t°		
	78·26% K	53·64% K	44·80% K

700	0·8824	1·0004	1·0452
800	0·8933	1·0810	1·0584

At each temperature from 100° to 800° the heat capacities of the liquid alloys correspond closely to those calculated additively from the values for pure liquid potassium and sodium. As with sodium, each liquid alloy shows a minimum in heat capacity between 500° and 650°C.

The equation $C = W_{Na}C_{Na} + W_{K}C_{K}$, where W_{Na}, W_{K} are the weight fractions of sodium and potassium in the alloy and C, C_{Na}, C_{K} the heat capacities of the alloy, pure sodium and pure potassium respectively, may be used to calculate the heat capacity of the alloy. Values have been taken from "Liquid Metals Handbook"[1] and are given in Table VIII.

In this temperature range, i.e. 280 – 295°K., the stable state of the system is solid sodium plus liquid alloy. Part of the excess heat capacity is probably due to a destruction of local order in the liquid alloy but the greater part seems to be produced by the heat of solution of sodium in the alloy, a process which is undoubtedly endothermal. The discrepancies in the two series of results show that the measurements above 280°K. do not refer to the system in an equilibrium state.

The Na_2K – K eutectic point has been established during the preparation of the alloy of composition Na_2K. The eutectic temperature is found to be −12·65±0·01°C. This may be compared with other values of −12·6, −12·5 and −12·3 reported by Van Bleiswijk,[33] Rinck[6] and Miller, Ewing, Hartman and Atkinson[34] respectively.

The incongruent melting point for Na_2K has been established as 6·90±0·00°C. Values of 6·90 and 6·6 were obtained by Van Bleiswijk and Rinck respectively.

Entropy changes of the alloy Na_2K for various temperature intervals are given in Table X.

TABLE X. ENTROPY CHANGES OF Na_2K FOR VARIOUS TEMPERATURE INTERVALS

Temperature Interval °K.	ΔS e.u./g.-atom
0 – 12 (extrap.)	0·012 ± 0·005
12 – 273·16	12·381 ± 0·009

Phase transformation at 280·06	2·50 ± 0·04
0 – 273·16	12·48 ± 0·02
0 – 280·06 (solid)	12·67 ± 0·02
0 – 280·06 (2 phase)	15·17 ± 0·06
0 – 298·16 (liquid)	16·07 ± 0·03
0 – 320 (liquid)	16·66 ± 0·03

The residual entropy of the alloy Na_2K has been estimated by extending the data in Table X to 420°K. and using the data of Douglas et al.[31] This temperature has been chosen because both metals are liquids and the heat capacity per g. atom is independent of alloy composition. The system thus has one feature of an ideal solution. It is found that $S_{420°K.} - S_{0°K.} = 18{\cdot}74$ e.u./g.-atom. The entropy of ⅔ g.-atom of sodium and ⅓ g.-atom of potassium at this temperature is 17·42 e.u. If it is assumed that the entropy of mixing is nearly ideal, $\Delta S_{mixing} = 1{\cdot}27$ e.u./g.-atom. Thus $S_{420°K.}$ for the system is 18·69 e.u./g.-atom which gives a residual entropy of −0·05 e.u./g.-atom. This estimated negative value of the residual entropy suggests that the entropy of formation of Na_2K exceeds the ideal value calculated as the heat of mixing.

The assumption that the heat capacity of the alloy is additively related to the heat capacities of the components is considered to be without theoretical or experimental foundation. In the work cited the deviations from additivity are in some cases quite large and in most cases outside the experimental error.

The estimated residual entropy referred to above should be treated with caution until an experimental value for the entropy of formation of liquid alloy is obtained.

The heats of formation of sodium–potassium alloys have been determined by Kawakami[35] by measuring the heat change when the molten metals are mixed at 110°C.

The value obtained, −48 g.-cal. for 48·7 at.-% of sodium (the maximum point on a Q/x curve, where Q is the atomic internal heat of the mixture and x the at.-% composition) is lower than that given by McKisson and Bromley[36] who also measured directly the heat of mixing. Ketchen and Wallace[37] have determined the heats of formation from the measured heats of reaction of the alloys and the pure metals with water, i.e. the small heats of alloying have been obtained from large heats of solution. For the alloys Na_xK_y, where $x + y = 1$ g.-atom, the heats of formation expressed as g.-cal./g.-atom at 25°C. are 500±90, 820±90, 1150±120, 1100±60 and 800±80 for solid reactants and 60, 260, 590, 550, 230 for liquid reactants, for 37·41, 48·46, 62·10, 68·16 and 78·14 at.-% of potassium respectively.

Average values for the compositions, Na_2K, NaK and NaK_2 given by McKisson and Bromley[36] and considered to be the more accurate values[1,38] are at 25°C. 2130±100, at 110°C. 540±100, at 25°C. 1440±100, at 110°C. 370±100, at 25°C. 2130±100 and at 100°C. 540±100 g.-cal. per g. mole respectively.

The effect of atomic volume on the heat of formation of solid solutions of binary metallic systems has been studied by Heumann.[39] Binding energies are similar between partners which are chemically alike and so contribute little, if anything, to the heat of formation. The heat of formation is largely accounted for by the distortion energy. With the alkali metals, in spite of large volume differences, the distortion energies are small, so that all possible solid solutions are permissible.

A means for evaluating the entropies of fused sodium–potassium alloys is mentioned by Wallace et al. who discuss the applicability of chemical thermodynamics to the study of alloy formation.[40]

Volume increments of compounds for sodium with potassium are given by Biltz and Weibke.[41] The density of the alloy, Na_2K, is 0·8012 at 0°C. from which a corrected value of 87 is obtained for a molar volume. The sum of the atomic volumes is 89 and the compound increment 60.

Kubaschewski and Catterall[38] express the volume change on formation of the alloys by $\Delta V_T = [V \text{ alloy} - \Sigma V(\text{metals})] / \Sigma V(\text{metals})$ at $T°$. For 1 g.-atom of NaK_2 (i.e. ⅓ g.-mole of NaK_2), $\Delta V_{373} = -0{\cdot}007$ and $\Delta V_{673} = -0{\cdot}0095$. For 1 g.-atom of Na_2K, $\Delta V_{373} = -0{\cdot}010$ and $\Delta V_{673} = -0{\cdot}014$.

The thermal conductivities of two sodium–potassium alloys containing 56·5 and 77·7% potassium have been measured by Ewing, Seibold, Grand and Miller.[42] There is a good analogy between the thermal conductivity-temperature curves and the electrical conductivity-temperature curves. The calculated value of the Lorentz number approaches the theoretical value of $2{\cdot}45 \times 10^{-8}$ watt-ohm/°C.A.

Electrical resistance measurements have been made on alloys containing 44·3 and 80% of potassium by Drugas, Rehn and Wilkinson.[43]

The results obtained for the thermal conductivity and electrical resistance by these workers are cited in Liquid Metals Handbook[1] and given in Table XI.

Table XII gives the electrical resistivity figures reported by Rahiser, Werner and Jackson.[1,44]

The change of resistance of liquid sodium–potassium alloy at room temperature in magnetic fields up to 13,000 gauss has been studied by Fakidov and Kikoin[45] and found to follow a linear law even in weak fields.

For field strengths (H) greater than 1000 gauss, the relative change of resistance, $\Delta r/r$, with the magnetic field is represented by the equation: $\Delta r/r = aH + b$. This agrees with the results of Kapitza for solid metals but the straight-line portions of the curves start at a higher value of H for the liquid than for the solid state. For a field of 11,400 gauss $\Delta r/r = 6{\cdot}1 \times 10^{-4}$ at room temperatures and $2{\cdot}4 \times 10^{-4}$ at 100°C. The electrical properties of liquid metals are like those of solid metals; therefore conductivity of metals cannot be accounted for by assuming a periodic crystal lattice.[46] The use of very fine containing tubes is believed to minimize spurious effects due to motion in the liquid. The results of Fakidov and Kikoin have been confirmed and in addition it has been found that longitudinal magnetic fields produce a larger effect than transverse fields. For fields over 2000 gauss there is a straight line relationship between magneto resistance and field strength.[47,48]

The change of thermoelectromotive force and electrical conductivity of a sodium-potassium alloy in passing from the solid to the liquid state was investigated by Siebel in 1919.[49] The alloy studied melted at 6·5°C., had a density of 0·8871 at 18°C. and contained sodium and potassium in the ratio of their atomic weights. The thermoelectromotive force was determined against Constantan, one junction being kept at −37·9°, the other at −40° to 40°C. By plotting thermoelectromotive force against the absolute temperature, the slope of the curve below −10°C. is given by $dE/dT = 37 \times 10^{-6}$ volts, above 18° $dE/dT = 35{\cdot}3 \times 10^{-6}$ volts, while around the melting point there are three sharp breaks; the slope at the melting point is 70×10^{-6} volts. In passing from the solid to the liquid state there is a decrease of $1{\cdot}7 \times 10^{-6}$ volts in thermoelectromotive force. The electrical conductivity has been measured between −60° and 40°. Above 18° and below −20° the resistance is a linear function of temperature; the temperature coefficient $\alpha = 0{\cdot}0015$ and 0·0097 respectively. In the region of the melting point, i.e. between 6° and 8°C., α increases rapidly. If the number of electrons in 1 cc. of solid metal is N and the increase in volume during melting is γ per c.c. then $N' = N/(1 + \gamma)$ and is the number of electrons in 1 c.c. of liquid metal. As $dE/dT = (2R/F) \log N/N'$ and $\gamma = 0{\cdot}0098$ c.c. then $dE/dT = (2R/F) \log (1 + \gamma)$, which gives the potential difference between solid and liquid metal, $dE/dT = 1{\cdot}68 \times 10^{-6}$ volts, which corresponds closely with the experimental value of $1{\cdot}7 \times 10^{-6}$ volts.

Macdonald and Pearson,[50] have reported on the thermoelectric behaviour of sodium-potassium alloy, Na-K, below 80°K. Of the alkali metals and their alloys with each other, only sodium behaves according to the conventional electron transport theory. According to Domenicali and Otter,[51] the thermoelectric power in a metal depends on the details of how the current carriers in the metal are scattered by the various deviations of the crystal from a perfect lattice; the usefulness of thermoelectricity as a tool for studying the nature of lattice imperfection is briefly discussed. A semiempirical theory of thermoelectric power of metal alloys is described in which the absolute thermopower is related to the energy dependence of the scattering cross section of a lattice imperfection. The correlation with high temperature thermoelectric properties of binary alloys of the alkali metals is quite satisfactory but the low temperature properties cannot be properly discussed without further extensive experiments at very low temperatures.

Because of their relatively low melting points, high boiling points, thermal stability, low vapour pressure and high heat-transfer coefficients, sodium-potassium alloys are particularly suitable as heat-transfer liquids in heat exchange systems. Their pumping characteristics are comparable to those of water but their low specific heats require a larger weight of metal than of water to remove the same amount of heat with the same temperature difference.[1,52,53] They may be used as coolants for nuclear reactor plants and steam generation.[1,52,54,55]

Much of the data collected so far on the performance of sodium-potassium alloy in heat exchange systems has been based on experiments designed for application rather than for acquiring fundamental information and an account of the work so far carried out is given in Liquid Metals Handbook[1] which contains a considerable number of literature references. Heat transfer under various conditions with natural circulation or convection, such as would result owing to temperature gradient in a container, is discussed.

Data and diagrams for specific cases are given with references to the literature.[1] Hyman, Bonilla and Erlich[56] in their work on natural-convection transfer processes at horizontal cylinders deal with the effects of flow patterns resulting from various rates of heat transfer and emphasise the effect of wetting.

Heat transfer with forced convection is also fully discussed and results and diagrams for specific cases are given[1] with many literature references.

Katz[1] discusses heat transfer in a boiling sodium-potassium alloy system. Heat transfer by condensation is discussed with reference to sodium-potassium alloy by Bonilla.[1]

The presence of impurities in sodium-potassium alloy may accelerate corrosion, impair mechanical and thermal performance of equipment and when the alloy is used as a nuclear reactor coolant may induce radioactivity. At oxygen contents above 100 p.p.m. the corrosion rate for many materials is markedly increased; carbon and calcium affect corrosion to a lesser degree but calcium in sodium attacks nickel. There have been no apparent corrosive effects due to the other major impurities in sodium-potassium alloys, e.g. chlorine, lithium and mercury. Owing to the decreased solubility of sodium oxide in sodium-potassium alloy at lower temperatures, the oxide will deposit as a solid whenever the temperature falls below the solubility limit. For this reason the oxygen content should be limited to less than saturation at the lowest system temperature, preferably less than 10 - 20 p.p.m.. It is highly desirable to keep all other insoluble materials to a low value by filtration.

The sources of impurities in sodium–potassium alloy, their effects on the efficiency of the alloy as a liquid coolant, methods of internal and external sampling, analytical techniques for the determination of oxygen, potassium, calcium, carbon, hydrogen, metals other than the alkali metals, purification by filtration, chemical means and distillation are described in detail with many references.[1]

Since sodium–potassium alloy reacts with oxygen and moisture it is necessary to protect the alloy by the use of an inert gas, such as nitrogen, argon or helium. For reasons already mentioned, the inert gas must contain as little oxygen as possible; hydrogen will tend to form hydrides which will result in plugging; water vapour is a source of oxygen and hydrogen; the presence of hydrocarbons in the inert gas results in "cracking" at high temperatures with consequent addition of hydrogen to the system. Also steel will be carburized; at temperatures up to 1000°F. with reasonable amounts of hydrocarbons the carburization will only be of the order of a mil in depth but this might affect certain equipment.

Although nitrogen, argon and helium are not appreciably soluble in sodium–potassium alloy they may be entrained as gas bubbles. Helium alone does not become radioactive but argon on the other hand has a substantial cross section and emits beta and gamma radiation with a half life of 1·82 h. Nitrogen is better than argon owing to the short half life of 7·3 sec. for ^{16}N.

A reactor coolant system becomes radioactive as a result of reactor operation. The radioactive material in the system will emit both gamma and beta rays but nearly all the beta radiation will be absorbed by the pipe walls. Kendall and Grand discuss the radioactive material transfer which occurs in reactor coolant systems.[1]

Fleischmann and Koenig[1] give an account of the factors which must be taken into account when choosing materials of construction and methods of fabrication for sodium–potassium coolant systems.

Since there is little thermal resistance in the liquid alloy film, the total temperature difference between the liquid alloy temperature and the temperature on the other side of the wall of the containing vessel occurs within the dividing metal wall causing stresses due to differences in thermal expansion proportional to the temperature difference. The maximum thermal stress decreases with increasing thermal conductivity of the structural material and increases with increasing surface heat transfer coefficient and wall thickness.

Another important factor in the design of a heat transfer system using sodium–potassium alloy as a coolant is the resistance of the structural materials to corrosion. A choice has to be made between corrosion-resistant materials having low thermal conductivity and high coefficients of expansion, and the less corrosion-resistant materials with better thermal properties. Fatigue failure of structural materials must also be considered because of the severe thermal stress involved. All these points as well as safety and fire precautions are discussed in detail.[1]

The measurement of heat-transfer coefficients in a double annulus heat exchanger with sodium–potassium alloy as coolant has been carried out by Hall and Jenkins.[57] The performance of small liquid sodium–potassium heat exchangers has been assessed by Tidball.[58] Trocki and Bruggeman[59] give an account of the use of sodium–potassium alloy for reactor cooling and steam generation and discuss the heat transfer, chemical and corrosion effects and describe the pumps, valves and instruments used in the system. Trocki, Bruggeman and Crever[55] describe fluid handling of sodium–potassium alloy for reactor cooling and steam generation. Many other papers also deal with the subject[60–64, 52–54] and with pumping systems for liquid sodium–potassium alloy.[65–68]

Corrosive effects of sodium–potassium alloy on various materials at high temperatures, i.e. up to 800°C., have been studied by Kelman.[69] Uranium, thorium, beryllium and niobium show extremely good resistance; the presence of oxygen in the alloy affects the corrosion resistance of these metals adversely. The presence of chromium and high-chromium alloys greatly accelerates the attack upon steel by sodium–potassium alloy. Nickel and high-nickel alloys show extremely good resistance. Generally copper and its alloys, carbon, silicon, silver and platinum are extensively attacked by sodium–potassium alloy. The corrosion of low alloy steel in hot sodium–potassium alloy has been studied by Milich and King.[70] Specimens of AISI 347 pipe and pipe welds have been subjected to repeated thermal shocks by quenching the inner surface with cool sodium–potassium alloy; it would appear to be safe to use current design methods where stresses caused by thermal shock are not in excess of those reported by Tidball and Shrut.[71]

The use of sodium–potassium alloys as coolants in arc and vacuum melting in titanium metallurgy is discussed by Cooper and Herres;[72] the alloys do not explode when in contact with molten titanium. The term "advantage factor" is used by Convey[73] to compare various coolants for use in atomic reactors: the "advantage factors" of water, liquid sodium, 78% potassium–22% sodium eutectic, liquid lead, liquid bismuth and liquid lithium are $3{\cdot}3 \times 10^4$, $2{\cdot}3 \times 10^{13}$, $2{\cdot}4 \times 10^{11}$, $1{\cdot}3 \times 10^{10}$, $4{\cdot}6 \times 10^{14}$, and $5{\cdot}0 \times 10^{14}$, respectively.

An alloy of sodium and potassium, liquid at −12°C. may be moved by a magnetic field acting on it while it is traversed by an electric current and use is made of this property in pumping or compressing systems such as those of refrigerators.[74]

The thermal, chemical and radiation hazards of liquid sodium–potassium alloy are reviewed by Finkel and Lyons.[75]

The results of some 'wetting' tests are given in Table XIII. During the lowering of the sample to make contact with the specified metal the meniscus between the alloy and the metal is observed and the temperature at which the metal surface is 'wetted', noted. A depressed meniscus is recorded as not 'wetting' whereas a flat or raised meniscus at the metal surface is described as 'wetting'.[24]

TABLE XIII. 'WETTING' OF METAL SURFACES BY SODIUM–POTASSIUM ALLOY

Metal Surface	Temperature of 'Wetting' °C.		
	30% wt. K	45% wt. K	65% wt. K
Soft Iron	270	295	310
Stainless Steel	260	290	320
Nichrome	320	330	340
Nickel	345	320	350

The *X*-ray diffraction haloes exhibited by different proportions of sodium and potassium in sodium–potassium alloys have been studied by Banerjee.[76] The alloys are regarded as solutions of an excess of sodium or potassium in the liquid compound Na_2K. When the amount of dissolved metal is small the halo is nearly the same as that of Na_2K; when one of the metals preponderates the halo is practically that of the preponderant metal. Alloys of intermediate composition give haloes in which the effects of the excess metal and the compound Na_2K are superimposed. It appears that the three atoms in the compound Na_2K are situated at the corners of a triangle. A faint inner ring is observed where the excess of either metal is small.

Monochromatic *X*-ray diffraction patterns of liquid sodium–potassium alloys at 115°C. have been prepared by Gingrich and Henderson and plots of position of main peak versus composition constructed. There is no indication of the inflexion attributed to Na_2K molecules in the liquid by previous work.[77]

Heaps[78] has shown that the intensity of X-ray scattering by liquid sodium-potassium alloy is not changed by as much as 2% in a field of 2700 gauss. There is no volume change of as much as 3×10^{-7} in a field of 7800 gauss. The increased resistance in a magnetic field found by Armstrong[47] cannot be due to changes in molecular grouping.

The optical constants of sodium-potassium alloys containing 11 - 76% of potassium have been measured by Morgan.[79] For an alloy of composition NaK the refractivity is at a maximum value of 0·137, the absorptive index at a minimum value of 12·5. A change in temperature causes a change in optical constants for some of the alloys but not for all.

In Table XIV n and κ refer to the mean values of the index of refraction and index of absorption for green light 5461A. and are considered to be within 10% of the true values. The reflecting power R has been calculated from the mean values of n and κ. The index of refraction is from air to water.

TABLE XIV. OPTICAL CONSTANTS FOR SODIUM-POTASSIUM ALLOYS

Wt.-% K	At.-% K	n	κ	R
17·3	11·0	0·081	27·2	94·6
36·2	25·1	0·100	18·5	91·4
45·0	32·5	0·108	16·8	90·4
55	41·8	0·115	15·6	89·7
66	53·3	0·137	12·5	87·0
74·2	62·7	0·124	12·8	86·9
84·3	76·0	0·088	17·6	90·2

Although there is a marked change in n and κ for the solid alloy containing 82·7% Na and 17·3% K on increase of temperature, it is probably due to the process of fusion since the optical constants for the liquid alloys appear to be unaffected by change in temperature.

Kent[80] has used the optical data of Morgan to compute for sodium-potassium alloys the number of free electrons per atom and the frequency of impact of the free electrons with molecules. The number of free electrons per atom is found to be 1·5 for most alloys with a value of 1·2 for NaK_2. The frequency of impact of the free electrons with molecules is of the order of $1-3 \times 10^{14}$ per second; it increases linearly with the increase in percentage of either constituent to a maximum for the compound NaK. Resistivity computed from optical data agrees within experimental error with experimental data for two of the alloys.

The existence of intermetallic compounds in the vapour state has been shown by a study of the spectra of the alloys of the alkali metals with each other. The observed bands for the molecule, NaK, lie near the principal series lines of the constituent atoms.[81]

Calculation of the dependence of the lattice constant of binary solid solutions on the composition is described by Orlov,[82] and an expression is derived for solid solutions of the alkali metals.

In agreement with the most frequently observed behaviour, the theory predicts a growth of the lattice constant with increasing concentration (at low concentrations) of the metal with the smaller radius.

Electrolysis of sodium-potassium alloy has been studied by Kremann and Rehenburg.[83] An alloy containing 70% of potassium and 30% of sodium, liquid at room temperature, is placed in a 1 mm. capillary tube and electrolyzed at 100°C. using copper electrodes at a maximum current density of 7·2 amp./sq. mm. At the end of 4 hr. the capillary is cooled, broken up into lengths and analysed. The concentration of sodium is found to increase at the anode, that of potassium at the cathode. The percentage difference in composition increases with current density, the increase in potassium concentration at the cathode being 10% at 1·4 amp./sq.mm. 24·5% at 4·45 amp./sq.mm. and 32·15% at 7·17 amp./sq.mm.

Photoelectric emission in sodium-potassium alloys has been studied by Ives and Stilwell.[84] The entire series of alloys has been investigated with respect to the relative values of the photoelectric currents produced by light polarized with the electric vector in and at right angles to the plane of incidence. The pure molten metals give values below 3 for the ratio of the two emissions; the alloys give three maxima at 20, 50 and 95% sodium with values of 10–30 for the ratio of the two emissions; the low values of the minima between the peaks approximate to those for the pure metals.

Emission of electrons by sodium-potassium alloys under the influence of chemical action is described by Richardson et al.[85-89] The alloys are subjected to the action of phosgene, chlorine, water vapour, nitrosyl chloride, carbonyl sulphide, bromine, iodine, thionyl chloride, sulphur chloride, sulphuryl chloride and mercuric chloride at low pressure when electrons are emitted. Energy distribution curves are given at pressures in the range of 10^{-6} to 10^{-3} mm.; with hydrogen chloride and water the emission is small but probably real; with nitrous oxide it is very small and probably zero. Current and pressure curves are given for chlorine, nitrosyl chloride, carbonyl sulphide, current and time curves are given for chlorine. Maximum electron energies are equal to the difference between the chemical energy available in the reaction and the work function of the alloy if the reactions with chlorine, nitrosyl chloride, or phosgene occur in one stage and with bromine and iodine in two stages: $M + COCl_2 \rightarrow 2Cl^-$ adsorbed on $M + (CO)$; $M + (NOCl) \rightarrow Cl^-$ adsorbed on $M + (NO)$; $M + Cl_2 \rightarrow 2Cl^-$ adsorbed on M; $M + Br_2 \rightarrow Br^-$ adsorbed on $M + (Br)$; $M + (Br) \rightarrow Br^-$ adsorbed on M; $M + I_2 \rightarrow I^-$ adsorbed on $M + (I)$; $M + (I) \rightarrow I^-$ adsorbed on M. It is assumed that a polar bond is first formed and stabilized with a three-body collision with the free metallic electron which then carries away the surplus reaction energy. These experiments may have some importance in connection with the kinetics of heterogeneous chemical reactions.

Sodium-potassium alloys are generally more reactive than sodium. Whereas sodium is oxidized at room temperature to sodium monoxide, potassium oxidizes finally to the superoxide, KO_2. The oxide which precipitates from solution in sodium-potassium alloys at 200°C. is however entirely sodium monoxide.[1] Oxygen may be removed from commercial hydrogen, nitrogen and argon by passing the gas through a trap containing liquid sodium-potassium alloy, 25% Na, 75% K. Water vapour may also be removed in this way.[90,91] The solubility of oxygen in sodium-potassium alloys approximates to the ideal value in the temperature range 20°–176°C. but the partial heat of solution changes at 260°–270°C.[92] Oxygen may be determined in sodium-potassium alloy by the butyl bromide method for determining oxygen in sodium, with certain modifications.[93]

Vapour phase combustion of sodium-potassium alloy containing 60% potassium yields a mixture of sodium peroxide and potassium superoxide, KO_2, commonly referred to as "MOX."[94]

Sodium-potassium alloys containing 25–90% of potassium, which remain liquid at room temperature and are ordinarily oxidized readily on exposure to air, may be kept as lustrous alloys in sealed tubes by the procedure earlier described for sodium (see page 460).[95]

The reaction of sodium-potassium alloy with water in the presence or absence of oxygen has been carried out by rapidly mixing the reactants by applying pressure to pistons and forcing the reactants through two opposing jets into the mixing chamber. An improved apparatus capable of contacting 1 ml. of each reactant in 2 msec. has been described. In the presence of oxygen two pressure waves are observed by a pressure-recording system. When the excess of water relative to alloy is reduced sufficiently, ignition occurs and only one maximum corresponding to the second pressure wave is observed. Only the first pressure wave is recorded when oxygen is absent.[96]

Ketchen and Wallace[37] give the heats of reaction of sodium-potassium alloys with water reproduced in Table XV: Alloy (l) + ∞H_2O = mixed hydroxides (∞H_2O) + $0{\cdot}5H_2$.

TABLE XV. HEATS OF REACTION OF Na-K ALLOYS WITH WATER AT 25°C.

At.-% K	$-\Delta H^{\circ}_{298}$ g.-cal./g.mol.
37·41 ± 0·06	45,190 ± 70
48·46 ± 0·10	46,550 ± 80
62·10 ± 0·07	47,260 ± 100
68·16 ± 0·14	47,390 ± 40
78·14 ± 0·29	47,370 ± 60

The half-time of the reaction between sodium-potassium alloy and ethyl alcohol is found to be several milliseconds. The reaction is carried out in an apparatus especially designed for the measurement of the rates of rapid reactions; a constant volume bomb with provision for rapid mixing is used and the progress of the reaction is observed by pressure changes using a strain gauge and a cathode-ray oscilloscope.[97]

When an electric discharge is passed through nitrogen and hydrogen, with sodium-potassium alloy present in the discharge tube either as cathode or anode, absorption of the gases takes place. Similar absorption occurs when the gases are ionised by alpha rays from polonium. The formation of nitrides and hydrides has been proved by chemical analysis. With nitrogen the effect of increase of temperature up to 200°C. is nil but above this temperature absorption increases.[98,99]

The apparatus used by Newman[98,99] for the absorption of hydrogen by sodium and potassium in the electric discharge tube has been modified in order to increase the amount of gas absorbed so that the amount of the reaction products would be sufficient for analysis. At a temperature of −40°C. and a voltage of 600 volts a thin white crystalline coating is formed on the surface of the alloy but as the reaction continues the coating becomes dark grey. A mixture of sodium and potassium hydrides is formed. The black deposit, earlier attributed to the hydrides, has now been shown to be a mixture of suboxides of sodium and potassium. Water is considered to be formed from the glass during the passage of an electric discharge through a vacuum vessel and is not wholly retained by a trap at −40°C. since the vapour pressure of water at this temperature is 0·1 mm. Hg. The black deposit fouling the surface of the alloy is quite unlike the white crystalline layer of sodium and potassium hydrides.[100]

Sodium-potassium alloys are especially sensitive to impact with tri- and tetra-chloromethane, tribromomethane and tetra- and penta-chloroethane. The last three halogen compounds and sodium-potassium alloy have been known to explode even on standing at ordinary temperatures.[101] The explosive action of sodium-potassium alloy on detonation with methyl chloride, methylene chloride and chloroform is described by Staudinger as moderately strong, strong and very strong respectively.[102]

Cueilleron[103] has shown that a mixture of sodium or potassium and a halide of a metal or metalloid (except those of the alkali or alkaline earth metals) explodes when subjected to shock by striking with a hammer. Explosive reactions also occur in general with oxygen-containing compounds (see page 497). The power of the explosion decreases in the order: sodium-potassium alloy, potassium, sodium, lithium, barium.

Sodium-potassium alloys react explosively with solid carbon dioxide;[104,105]

violent reactions also occur with water, carbon tetrachloride, sodium bicarbonate and foam type extinguishers. In no case should a can sealed with solder be used to contain sodium-potassium alloy.[105]

A violent explosion occurs when oxalyl chloride or bromide is treated with sodium-potassium alloy.[106]

Reactions of sodium-potassium alloy with alkyl halides are described by Hückel, Kraemer and Thiele.[107] Methyl bromide and sodium-potassium alloy in xylene give 12·5% ethane; ethyl bromide gives 28% ethane and 40% butane; a mixture of methyl and ethyl bromides in xylene with the alloy at 20°–30° C. yields ethane, ethylene, propane and butane. Propyl bromide under the same conditions gives 8–11·5% of propane, 6–7·5% of propene and 55–65% of hexane. A mixture of methyl bromide and propyl bromide in xylene with sodium-potassium alloy yields ethane, propene, butane and hexane. *iso*Propyl bromide is converted to 45% of propane and 10% of propene; a mixture of methyl bromide and *iso*propyl bromide gives ethane, propene and *iso*butane. *iso*-Propyl bromide and sodium-potassium alloy in decalin are converted to 27·5% propane and 25% propene; in benzene solution 40% of propane and 31·5% of propene are obtained. Methyl chloride does not react with sodium-potassium alloy in xylene; ethyl chloride gives 20·5–32% of ethane, 2–5·5% of ethylene and 3·3–16% of butane. *iso*Propyl chloride and sodium-potassium alloy in xylene give 45% of propane and 10% of propene.

The action of sodium-potassium alloy on aliphatic, aromatic and mixed ethers has been studied by Durand.[108] The liquid alloy reacts more vigorously than sodium, particularly in the cold.

Sodium-potassium alloy attacks silicon;[1] a crystalline substance, NaSi, is formed which inflames in air; if heated under reduced pressure the compound decomposes into sodium and silicon.[108a]

Reactions of organosilanes with sodium-potassium alloy are described by Benkeser et al.[109] Diphenylsilane, Ph_2SiH_2, and monophenylsilane, $PhSiH_3$, react with sodium-potassium alloy by a mechanism different from that ascribed to the reaction of triphenylsilane, where the reactive intermediate is Ph_3SiK. Examples of the reactions are given.

Hexaphenyldisilane is readily cleaved by sodium-potassium alloy in glycol dimethyl ether, $(CH_2OCH_3)_2$ and the potassium derivative formed, Ph_3SiK, is soluble in glycol dimethyl ether but insoluble in ether.[110]

The dimethyl ether of ethylene glycol, when treated with sodium-potassium alloy, is found to contain sodium in solution.[111]

The reduction of titanium tetrachloride with sodium-potassium alloy has already been mentioned (see page 402).

The conductivities of sodium and potassium in dilute liquid ammonia show no evidence of compound formation between the metals.

Conductivities and solubility relations in the ternary system, Na–K–NH_3, have been given for the range −40° to +70° C.[112]

The carbon content of sodium-potassium alloys is determined by igniting a 100 mg. sample in oxygen and absorbing and weighing the carbon dioxide formed. The procedures for sampling the hot alloy from a dynamic system, and transferring the sample to specially designed analytical equipment have been described.[113,114]

To obtain solutions of sodium-potassium alloys for analysis the alloys may be frozen in a borosilicate glass dish on solid carbon dioxide and then added to a slurry of alcohol and solid carbon dioxide[115] or the alloy may be placed in a beaker and blanketed with helium or argon, using an inverted funnel for the purpose, and *n*-hexane added to cover the alloy which is then treated drop-wise with methyl or ethyl alcohol.[116]

The partial pressure of mercury vapour in a vacuum tube may be reduced to 10^{-5}, (or by using special diaphragms to 10^{-6} mm. Hg) by means of sodium-potassium alloy (30:1) as a getter. The alloy is vapourised in a vacuum to condense on a surface and is found to capture 30% of vapourized mercury molecules with practically no impairment of the activity after a fair amount of compounds have been formed on the surface.[117]

The system sodium–potassium–mercury has been examined by Jänecke[118] and constitutional diagrams prepared. The double compound, NaKHg, m.p. 188°C., has been isolated and crystallized in the form of blue, glistening hexagonal prisms.

Halla[119] has calculated the free energy of formation from the ternary phase diagram of the system Na–K–Hg for the reaction: $NaKHg_2 \rightarrow NaHg + KHg$ and gives values of ΔF° at 100° and 150°C. respectively as 809 and 856g.-cal./mole.

An equation has been used by Wagner[120] to determine the change in activity of metal 2 dissolved in metal 1 due to the addition of a solute metal 3. It is necessary that the changes in the activity coefficients with composition for the binary systems 1–2 and 1–3 be known, and that the interaction between positively charged metal ions is of minor importance as compared with the effects due to a change in the chemical potential of the electrons. The system sodium–potassium–mercury has been studied. In the binary system Hg–Na, $d\ln\gamma_{Na}/dx_{Na}$ has been found from the literature to be 36·0, where γ refers to the activity coefficient and x the molar fraction. In the binary system, Hg–K, $d\ln\gamma_K/dx_K = 67{\cdot}0$, $d\ln\gamma_{Na}/dx_K = d\ln\gamma_K/dx_{Na}$ from which:-

$$d\ln\gamma_{Na}/dx_K = \pm\left[\frac{d\ln\gamma_{Na}}{dx_{Na}}\cdot\frac{d\ln\gamma_K}{dx_K}\right]^{1/2}$$

and the calculated value for $d\ln\gamma_{Na}/dx_K$ is therefore 49·1. A study of the reaction: $Na(\text{in } Hg) + K^+(aq.) = K(\text{in } Hg) + Na^+(aq.)$ by other workers gives an experimental value of $d\ln\gamma_{Na}/dx_K = 46{\cdot}5$.

The compound KCd_3 in the form of needle-like crystals, m.p. >550° is indicated in the system Na–K–Cd–Hg.[118]

The sodium–rubidium system has been described by Rinck,[121] Goria,[122] Böhm and Klemm[5] and Klemm.[4,123]

The solidification diagram for sodium–rubidium shows the absence of solid solutions and of compound formation; there is no compound, Na_2Rb, analogous to Na_2K in the sodium-potassium system. A eutectic occurs at 75 at.-% of rubidium at −4·5°C.,[121] −5·2°C.[122] Although the curve tends to become horizontal in the vicinity of the composition corresponding with Na_2Rb, neither thermal analysis nor *X*-ray studies have indicated that such a compound exists. The solubility of rubidium in sodium is given approximately by the expression $W = 132{\cdot}2 - 1{\cdot}356t$ down to 61°C., i.e. 50% rubidium,[1] where W = wt. % and t degrees Centigrade.

The relative magnitude of the liquidus depressions in the sodium–rubidium system has been accounted for and the composition of the eutectic interpreted by calculations made by Henry, Jaswon and Raynor in their work on the cohesion of alloys.[11]

Determinations of the molecular weight of rubidium by cryoscopic measurements in sodium give a value of 104 indicating that 22% of diatomic rubidium, Rb_2, is present; sodium in rubidium is monatomic.[7]

Thermal neutron absorption cross sections of rubidium are significantly lower than those for potassium; sodium–rubidium alloys would in this respect be especially suitable as coolants for atomic reactors. The macroscopic physical properties of these alloys are similar to those of sodium–potassium alloys.[124]

The phase diagram[125,126] is shown in Fig. 2.

The sodium–cæsium system has been described by Rinck,[7] Böhm and

Klemm,[5] Goria[127] and Klemm.[4,123] Thermal analysis shows a eutectic at -30°C. and at 75 at.-% of cæsium, a transition point at -8°C. and 71 at.-% of cæsium, and an indication of the compound Na_2Cs.

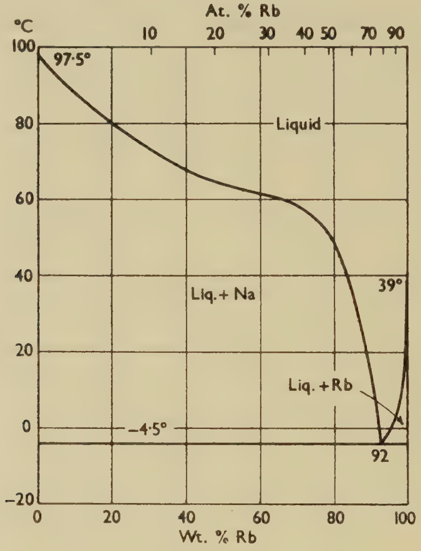

FIG. 2. EQUILIBRIUM DIAGRAM Na-Rb

The volume contraction on alloying is less than 5%.[5] The magnetic susceptibility of the alkali metal alloys has been measured at various temperatures and the formation of compounds or mixed crystals in the sodium-potassium, sodium-cæsium and potassium-cæsium systems is found to decrease the magnetic susceptibility.[5] Henry and Raynor[11] in their work on the cohesion of alloys state that for cases of mutual solid solubility of the two components of a binary alloy, the wider solution should be formed where the smaller ion is dissolving in the solvent having the larger ion. The possible effect on solid solubility relations of the mutual distortion of the electron clouds of the component ions is considered. Calculations made for the alloys of the alkali metals give results in good agreement with the experimental data and show that solid solution formation is restricted in all the possible systems except potassium-rubidium, potassium-cæsium and rubidium-cæsium. The relative magnitudes of the liquidus depression in the sodium-cæsium system and the composition of the eutectic are accounted for. Cæsium lowers the melting point of sodium, and the solubility as wt.-% of cæsium in sodium up to 50% of cæsium (80°C.) is given approximately by the expression: $W = 223 - 2{\cdot}29t$ where t is the temperature in degrees Centigrade.[1]

Cryoscopic measurements in sodium to determine the molecular weight of cæsium give a value of 218 indicating the presence of 64% of cæsium in the diatomic form Cs_2. Sodium in cæsium is monatomic.[7]

The phase diagram[125,126] is shown in Fig. 3.

Copper has been recrystallized from sodium at 550°C. The resistance of copper to sodium is good up to 300°-400°C.[1] but it is not recommended as a constructional material for sodium-handling equipment for permanent usage.[128] No indication of the existence of a copper-sodium compound is given when a solution of sodium in liquid ammonia is titrated with a solution of copper iodide in liquid ammonia. A black precipitate of metallic copper is formed with perhaps a slight amount of sodium, and the supernatant liquid is decolourized.[129] A violent reaction occurs when sodium is used to reduce liquid copper containing 1·35% oxygen at 1150°C.[130]

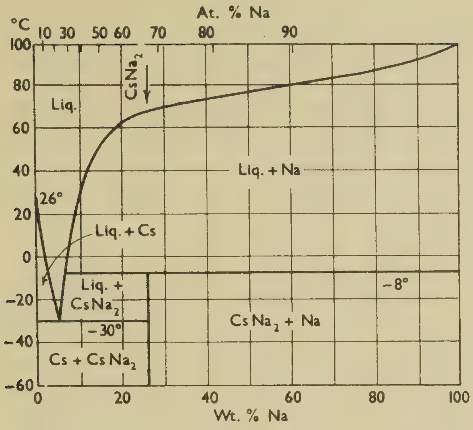

FIG. 3. EQUILIBRIUM DIAGRAM Na–Cs

Sodium is miscible with silver in all proportions. The solubility of silver in sodium up to 650°C. (40% Ag) is given as wt.-% by the expression: $W = -2{\cdot}4 + 0{\cdot}0180t + 7{\cdot}007 \times 10^{-5}t^2$, where t is the temperature in degrees centigrade.[1] Zintl and Brauer[131] by melting together silver with 50 at.-% of sodium obtained a very inhomogeneous alloy with the low hardness of metallic sodium. The reactions of silver salts in liquid ammonia solutions of sodium have been studied by potentiometric titrations, (see page 514). No compound of silver and sodium is formed but silver is precipitated from solution.

Reactions at high temperatures between air and liquid metal solutions containing sodium have been studied by ejecting the heated alloy downward through a small orifice into a large steel chamber previously evacuated and filled with dry air. The amount of oxygen present is 3–30 times that required for complete oxidation of the sodium present and the time of flight of the jet so short that only a fraction of the sodium present can react. The sodium-silver system containing 0·1 mole fraction of sodium in dry air at 700°C. is quite reactive.[132]

The phase diagram[125,126] is shown in Fig. 4.

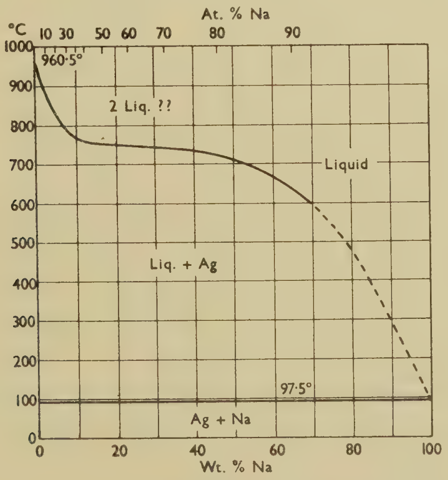

FIG. 4. EQUILIBRIUM DIAGRAM Na–Ag

Gold is miscible with sodium in all proportions; the eutectic containing 22·5% of gold melts at 82°C. The experimental data are represented by the expression: $\log(1 - W/100) = 2{\cdot}5094 - 930{\cdot}25/T$ from the m.p. of sodium down to the eutectic where W is the wt.-% of gold in sodium and T the temperature in °K.[1]

Potentiometric titrations of a solution of sodium in liquid ammonia with a solution of gold iodide in the same solvent show a point of inflexion shortly after the solution is decolourized when the composition of the mixture corresponds to NaAu. Towards the end of the titration a slow steep rise of the potential marks the separation of free gold.[129]

The compound $NaAu_2$ is shown in the phase diagram Fig. 5.[125] Quadt, Weibke and Biltz[133] have obtained the compound $NaAu_2$ by heating fine gold powder with sodium at 250° under high vacuum for several hours in a tube previously filled with argon. Excess sodium is distilled off at 300°–460°. The compound $NaAu_2$ is a bright brass yellow in appearance, stable in air but decomposing slowly at 700°C. An X-ray spectrum has been obtained: the compound crystallizes in the cubic system with 24 atoms per unit cell; a = 7·79A. Perlitz and Aruja[134] give a value of 7·7874 ± 0·0002A. at 20°C. for the side of the elementary cube of the compound $NaAu_2$ and 7·770A. for the side of the cube of the alloy Au(85·7) Na(14·3).

The spatial compression of sodium on combination with gold has been studied by Biltz et al[135] in view of the great differences in the densities of the metals. The space occupied by the alkali metals in their alloys with gold is much less than that occupied by the pure metals; this is regarded as being due to compression.

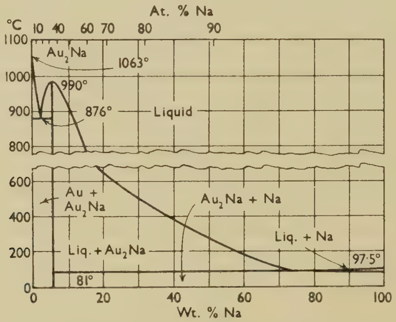

FIG. 5. EQUILIBRIUM DIAGRAM Na–Au

When sodium combines with gold to form aurides, the increase in molecular volume per atom of sodium is only 16· whereas in alloys of sodium with mercury, tin, lead, cadmium the volume increment for sodium is 17.

Beryllium alloys have been prepared by treating molten copper, nickel, iron or aluminium with an alkali metal and with a double fluoride of beryllium and an alkali metal.[136] Beryllium chloride, dissolved in sodium chloride to reduce evaporation losses, is reduced with sodium in the presence of aluminium to give alloys containing up to 10% of beryllium.[137]

Magnesium alloys to a very slight extent with sodium.[138] The magnesium sodium eutectic lies very close to the pure sodium end of the phase diagram; the solubility of magnesium in sodium expressed as wt.-% is given approximately by the expression: $W = -0{\cdot}27 + 0{\cdot}002775t$ up to 700°C., i.e. 1·67% of magnesium.[1] From the phase diagram given in Fig. 6[125,126] the solidifying point of magnesium is seen to be lowered by 2% of sodium to 638°–640°C.; the composition of the sodium-rich melt in equilibrium with the 2% melt and magnesium at 638°C. has been shown by analyses to be 98·5% sodium.

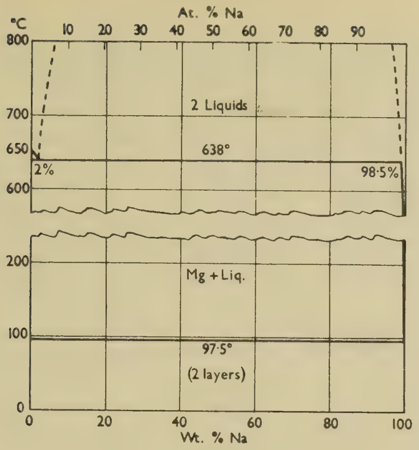

FIG. 6. EQUILIBRIUM DIAGRAM Na–Mg

Calcium–sodium alloys, obtained as a by-product in the Downs cell, can be converted into free sodium and calcium–magnesium alloys by heating with magnesium.[137] Sodium reduction of fused calcium chloride in the presence of magnesium under a protecting atmosphere results in the formation of magnesium–calcium alloys: $2Na + CaCl_2 + Mg = Mg/Ca + 2NaCl$.[139]

The influence of sodium on the mechanical properties of magnesium alloys is discussed by Lugaskov.[139]

Calcium is only partially miscible with sodium; the solubility of calcium in sodium up to 700°C., i.e. 9·4% calcium, is represented by the expression: $\log W = 2{\cdot}5629 - 1545{\cdot}6/T$ with a probable error of ±0·14% where W is the wt.-% of calcium in sodium and T the temperature in °K.[1]

Equilibria in fused salts, $Ca + 2NaCl \rightleftharpoons CaCl_2 + 2Na$, in which the metal phase consists of sodium–calcium alloys, have already been discussed in detail (see page 495). As sodium and calcium chlorides are insoluble in the metal phase, the presence of a salt phase in equilibrium with the metal phase has no influence on the composition of the latter.

Jellinek and Wolff[140] have examined the reaction of fused calcium and sodium chloride in a fire-brick crucible containing molten antimony or bismuth as electrode metals. If at.-% of metal is plotted as ordinates and mole % of its chloride as abscissae then: $x(1 - y)/(1 - x)y = k$. The equilibrium $Ca + 2NaCl \rightleftharpoons 2Na + CaCl_2$ is independent of temperature, cathode metal and even of the presence of water.

Lorenz and Winzer,[141] using pure sodium and calcium containing 1·2% of impurities, made up chiefly of silica, alumina and iron oxide, heated the elements in sealed steel bombs to avoid formation of calcium nitrides and hydrides and found that the limit of solubility of sodium in liquid calcium at 700°C. was 16 at.-% sodium and that of calcium in liquid sodium 0·8 at.-% calcium. Pure sodium was found to freeze out from all alloys studied at 97°C.

Rinck[142] has prepared a solidification diagram of calcium–sodium alloys and criticized the work of Lorenz and Winzer. The m.p. of calcium used by Lorenz and Winzer is given as 809°C.; it has been shown by Antropoff and Falk[143] and also by Rinck[142] that the presence of very small quantities of nitrogen lowers the m.p. of calcium considerably and that the true m.p. of pure calcium is in fact 851°C. (848° for sublimed calcium).

The solidification diagram is shown in Fig. 7 and the experimental results in Table XVI.

The liquidus shows a horizontal branch a–a'. Calcium and sodium are thus reciprocally miscible for mixtures containing between 4 and 77 at.-% of calcium. The composition of the heavy layer at 712°C. i.e. of the saturated solution of sodium in calcium at a' is 77 at.-% of calcium. The composition at point a, i.e. saturated solution of calcium in sodium at 712°, cannot be found accurately by cooling curves but a study of the 712°C. isotherm of the equilibrium reaction: $Ca + 2NaCl \rightleftharpoons 2Na + CaCl_2$ shows that point a corresponds to a solution containing 4 at.-% of calcium. Rinck's values differ considerably from those of Lorenz and Winzer who give the partial solubility limits as 0·8 and 86 at.-% of calcium and the temperature of the first horizontal as 700°C. On the branch aNa of the liquidus, Rinck confirms the existence of a eutectic approximating to pure sodium, it would appear that the weight of calcium dissolved in 100g. of sodium is 0·01g. at this eutectic. In Fig. 7 the area with respect to solid calcium is divided into two regions corresponding to two allotropic varieties of calcium. The heating curve of pure calcium shows a sharp change of internal energy at 450°C.; the alpha form of calcium is stable below 450°, the beta form between 450° and 848° the m.p. of calcium i.e. $Ca_\alpha \rightleftharpoons Ca_\beta - q$. For sodium-calcium alloys containing 90·55 to 35 at.-% calcium the transition temperatures are distributed between 394° and 446°C. respectively. The lowering of the transition temperature is due to lag phenomena and it is quite probable that the transition temperature is independent of the composition of the alloy.

At temperatures above 712°C. two liquid phases are present, saturated solution of calcium in sodium and saturated solution of sodium in calcium. In order to determine the composition of points, b, b', c, c', d, d' marked on the solidification diagram in Fig. 7 Rinck has made use of the data obtained from the isotherms at 850°, 975° and 1100°C. for the reaction: $Ca + 2NaCl \rightleftharpoons 2Na + CaCl_2$. A slight extrapolation shows that the two metals are miscible in all proportions at temperatures above 1180°C.

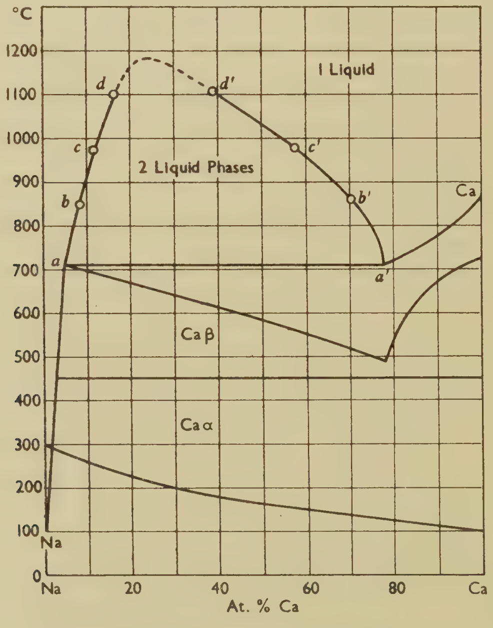

FIG. 7. EQUILIBRIUM DIAGRAM Na–Ca

According to Kroll[137] a calcium–sodium alloy containing 17% of sodium will stay in equilibrium with a salt bath containing 71% of calcium chloride at 850°C.: $CaCl_2 + 3Na \rightleftharpoons CaNa + 2NaCl$; by treating this alloy with large quantities of pure fused calcium chloride a nitrogen-free calcium may be obtained.

Calcium–sodium alloys containing 25–65% sodium can be separated by filtration[144] or vacuum distillation at elevated temperatures.[145] In the latter case sodium, sodium chloride and oxide-free calcium may be collected separately by using a heated condenser.

Calcium–sodium alloys containing 25–65% sodium, obtained as a by-product in the manufacture of sodium by the Downs process in which fused sodium chloride–calcium chloride is electrolyzed, may be used as a source of nitrogen-free calcium contaminated with only a few tenths of 1% of chloride and a few % of calcium oxide by treatment with ethyl alcohol.[137,146-148] The disposal of mixtures of metallic calcium and sodium by reaction with sodium hydroxide, is described by Padgett.[149]

The compositions of two bearing alloys containing calcium and sodium are roughly: (a) calcium 0·75–1·1; sodium 0·65–0·95; bismuth 0·10; antimony 0·25; magnesium 0·10; other metals 0·30% and the rest lead, (b) calcium 0·69; sodium 0·62; lithium 0·04, and lead 98·65%. The physical and mechanical properties such as hardness, corrosion resistance, limits of plastic flow, bonding strength with respect to the metal of the base, annealing temperatures are discussed. The abrasive resistance of these alloys compares favourably with that of a bearing alloy containing: tin 82, antimony 10·9, lead 3·1, copper 3·1%.[150]

Remy, Wolfrum and Haase[151] find that sodium is soluble in liquid strontium over the whole range of composition; it is not soluble in the solid state. No compound formation occurs but there is a eutectic at 92·5°C. and 3·2 at.-% of strontium.

Jellinek and Wolff[140] have studied the system: $Sr + 2NaCl \rightleftharpoons SrCl_2 + 2Na$ by electrolyzing the fused mixture in a fire-clay crucible with an antimony cathode. The equation to the curve obtained by plotting at.-% of metal as ordinate and mole % of its chloride as abscissa is: $x(1 - y)/(1 - x)y = K$. The equilibrium is not affected by temperature.

The solubility of barium in sodium is given by the expression: $\log W = 1{\cdot}2 - 0{\cdot}604 \times 10^3/T$ where W = wt.-% and T the temperature in °K. A solubility diagram is given below,[1] Fig. 8.

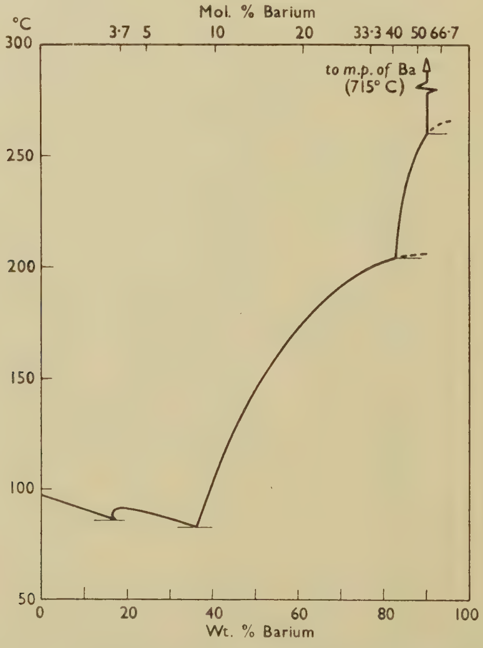

FIG. 8. BARIUM SOLUBILITY IN SODIUM

The phase diagram of the system, barium–sodium, has been prepared by Remy et al.,[151] c.f. Fig. 9. The equation does not appear to agree with the solubility diagram which is also different from Remy's phase diagram.

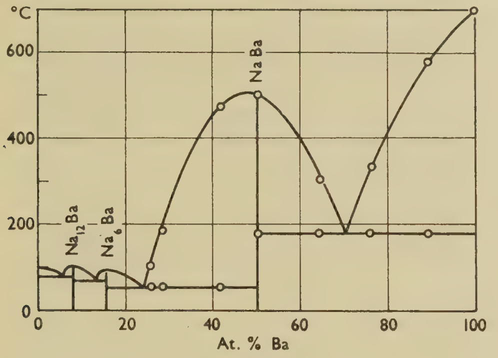

FIG. 9. EQUILIBRIUM DIAGRAM Na–Ba

Three compounds are shown, Na_2Ba, Na_6Ba and NaBa. There are also eutectics at 85°, 77°, 58° and 180° C.

The equilibrium $Ba + 2NaCl \rightleftharpoons BaCl_2 + 2Na$ has been studied by Jellinek and Wolff;[140] the fused mixture is electrolyzed in a fire-clay crucible with an electrode of tin, antimony or bismuth. The equation to the curve obtained by plotting at.-% of metal (ordinate) against mole % of chloride (abscissa) is: $x(1 - y)/(1 - x)y = k$. The equilibrium is quite independent of temperature, the cathode metal and even of the presence of water.

Zinc and sodium are only partially miscible;[1] at 557° C. zinc dissolves not more than 2·8% of sodium; when this alloy is solidified it consists of a zinc sodium compound in a zinc matrix.[137]

The electric potentials of sodium–zinc alloys have been measured by Kremann and Reiningshaus[152] who find that from 0–90% Zn the potential is practically the same as that of pure sodium. At 90% there is a drop of 1050 mV; from 92 to 98% of zinc the potential is practically constant at 400 mV. The authors assume the presence of a compound $NaZn_{12}$ in the sodium–zinc system, the potential of which is 1050 mV. "nobler" than sodium and 400 mV. less "noble" than zinc.

The reactions of sodium in liquid ammonia with solutions of zinc salts in the same solvent have already been described (see page 515). Kraus and Kurtz[153] and Burgess and Rose[154] found some indication of the presence of the compound $NaZn_4$; Zintl, Goubeau and Dullenkopf in their work on potentiometric titrations of sodium in liquid ammonia with liquid ammonia solutions of zinc iodide, obtained points of inflexion at compositions corresponding to $NaZn_{11·8}$ and $NaZn_{12·8}$ but were unable to confirm the presence of the compound $NaZn_4$.[129]

Zintl and Hauke[155,156] have since extracted a crystalline alloy of sodium and zinc with liquid ammonia and shown that it contains 2·6 wt.-% of sodium, i.e. it has the composition $NaZn_{13}$ and that it is a cubic compound with length of side a = 12·27A.; there are 112 atoms per unit cell and the alkali atom is surrounded by 24 equally distant zinc atoms. X-Ray, density and analytical data indicate unambiguously that the composition of the compound is $NaZn_{13}$. Powder diagram data are also given. Ketelaar[157] gives a = 12·25 A. for the side of the unit cell.

Sodium may be used to remove zinc after the desilverization of lead.[137] Ferrous metal such as sheet or wire may be coated with a zinc-sodium alloy containing up to 2% of sodium which serves to improve the quality of the coating.[158]

The phase diagram[125,126] is shown in Fig. 10.

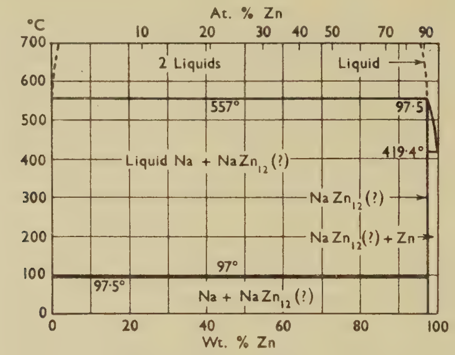

FIG. 10. EQUILIBRIUM DIAGRAM Na-Zn

The wetting of metallic zinc by liquid sodium has been investigated by Addison et al. by measuring contact angles over ranges of time and temperature. Electropolished zinc surfaces show a critical wetting temperature near 160°C.; chemical reaction between sodium and a zinc phosphate film deposited during electropolishing is considered to be responsible for this. No critical wetting temperature is observed for abraded zinc plates. The rates and mechanisms of wetting are discussed from the point of view of diffusion through surface films of zinc phosphate and zinc oxide and formation of the intermetallic compound $NaZn_{13}$. After removal of sodium by washing with water, microscopic examination of the surface indicates that the compound $NaZn_{13}$ reacts with water leaving behind zinc crystals without any major change in crystal form.[159]

Cadmium is miscible with sodium in all proportions. A simple eutectic is formed at 95·5°C. with 2·6% cadmium.[1]

Kremann and Reiningshaus[152] have measured the electric potential of cadmium-sodium alloys and found that from 0 to 66% of cadmium the potential is virtually that of pure sodium. At 66% the potential is decreased by 1300mV. and then remains constant to 80-85% when a further drop of 150 mV. is observed; the potential remains constant until 100% cadmium is reached. It is assumed from these results that the compounds $NaCd_2$ and $NaCd_5$ are responsible for the inflexions observed.

Kraus and Kurtz, by allowing cadmium iodide and cyanide in liquid ammonia to react with sodium in liquid ammonia, obtain rather inconclusive results for the ratio of sodium to cadmium in the reaction product, but conclude that the compound NaCd is probably formed.[153]

Zintl, Goubeau and Dullenkopf[129] (see also page 515) by potentiometric titrations of liquid ammonia solutions of cadmium iodide and sodium obtain results which appear to indicate that a compound of composition between Cd_5Na and Cd_7Na is formed under these conditions. The phase diagram given in Fig. 11[125,126] shows the presence of two intermetallic compounds $NaCd_2$ and $NaCd_6$. The crystal structure of the compound $NaCd_2$ has been investigated by Pauling[160] but the photographs are too complicated to assign indices with certainty to any of the spots. It may be that complex atom-groups are formed, as is the case in the formation of Pb_2 ions in a solution of sodium plumbide, $NaPb_2$, in liquid ammonia.

Kubaschewski and Catterall[38] critically review the thermochemical data obtained for the sodium-cadmium system by other workers and use some of the data to calculate the heat of formation, ΔH_{293} (g.-cal. per g. atom), latent heat of fusion (g.-cal. per g. atom), volume change on formation and partial free energies given in Tables XVII and XVIII.

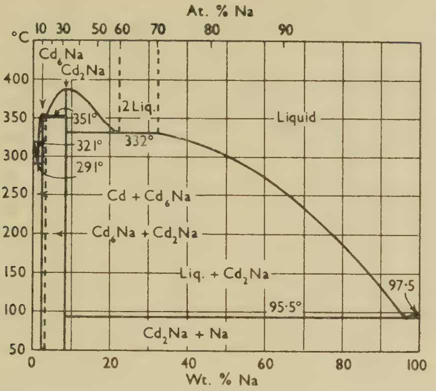

FIG. 11. EQUILIBRIUM DIAGRAM Na–Cd

TABLE XVII. THERMOCHEMICAL DATA FOR THE SODIUM-CADMIUM SYSTEM

	H_{293}	Lf	V_{298}
$\frac{1}{3}$ $NaCd_2$	−2800 ± 250	(1880)	−0·107
$\frac{1}{7}$ $NaCd_6$	−1800 ± 250	(1650)	−0·06

TABLE XVIII. PARTIAL FREE ENERGIES, SODIUM-CADMIUM SYSTEM

N_{Na}	$\Delta\bar{G}_{Na}$(668°K.)
0·15	−4150
0·20	−2660
0·3	−1450
0·4	−770
0·50	−430
0·60	−250
0·80	−175

The heats of fusion estimated from the duration of arrests on cooling curves are probably not accurate and are given in brackets. Possible values for the integral free energy for the composition $NaCd_2$, i.e. ΔG_{668}, for the heat of formation, $\Delta H_{liq.}$ and the integral entropy of solution, $\Delta S_{liq.}$ are −1480, −2150 g.-cal. per g. atom and −1·0 g.-cal. per degree/per g. atom respectively. For the intermetallic compound $NaCd_6$, $\Delta S_{liq.}$ = −0·4. There is some uncertainty in evaluating these properties so they should not be regarded as absolute values.

The solubility of cadmium in sodium is given by the expression $W = -16{\cdot}8 + 0{\cdot}203t$ where W = wt.-% and t = °C.[1]

The reaction between air and a jet of sodium solution in another metal is usually vigorous at high temperatures, accompanied by a flame, dense smoke of the reaction products and, where the sodium content is high, a mild explosion. Sodium–cadmium alloy containing 0·1 mole fraction of sodium tested at 700°C. in dry air at atmospheric pressure gives a vigorous reaction.[132]

Jänecke[118] has examined the system sodium–cadmium–mercury and has shown that the compounds $NaCd_2$, m.p. 385°, and $NaCd_4$, m.p. probably 360°, are present in the system. For the reaction: $2NaCdHg \rightarrow NaCd_2 + NaHg_2$, Halla has calculated the free energy of formation as 910 g.-cal./mole at 300°C.[119] The activity of sodium in liquid alloys, Na–Cd–Hg, of various compositions at 300°–400°C. has been derived from e.m.f. measurements; wide departure from ideal behaviour is found. The activity of mercury in the same system has been calculated from vapour pressure data and again wide departure from ideality is obtained.[161]

The data of Frauenschill and Hall[161] obtained at 400° C. have been used by Kubaschewski and Catterall[38] to calculate the partial free energies $\Delta\bar{G}_{\text{Na}}$ (liq.) and $\Delta\bar{G}_{\text{Hg}}$ (liq.). The integral free energies of mixing: N_{Na} (liq.) + N_{Hg} (liq.) + N_{Cd} (liq.) to form the liquid alloy i.e. ΔG_{673}, have also been calculated and are given in Table XIX. The energy values refer to g.-cal. per g. atom.

The compounds of sodium with mercury, their appearance and melting points have already been referred to (see page 440).

In his account of new methods and results on the detection of intermetallic compounds, Grube[162] refers to the melting points of the alkali mercurides and to their phase diagrams. The light alkali metals form compounds less rich in mercury than do the heavier ones, the limits ranging from Li_6Hg to $CsHg_{10}$; the alkali mercuric compounds containing the greatest amount of alkali metal are Li_6Hg, Na_3Hg, KHg. The m.p. of comparable alkali mercury compounds decrease with rising atomic number of the alkali metal. The compounds appear to be metals but are similar in their chemical properties to salts. They show a positive temperature coefficient of electrical conductivity and by "transport" work show a wandering of the ions. When the compounds are formed by melting the components together, the reaction is of a vigorously explosive type and much heat of reaction is produced.

Zviagincev[163] has suggested a method by means of which the composition of intermetallic compounds may be determined from the ionization potentials. If the ionization potential of metal A is denoted by J_A, i.e. the energy required to sever the ion from the atom, and the atomic volume by V_A, then the ratio J_A/V_A i.e. the atomic concentration of the ionization energy, will be different for different metals, and if metal B dissolves in metal A there will be places created in the crystalline lattice of the alloy where $J_A/V_A >$ or $< J_B/V_B$. This restrains the movement of electrons whereby the electrical conductivity is reduced. Solid solutions are always less conducting than pure metals.

Intermetallic compounds are characterized by maxima on composition–

electrical conductivity curves, and the author supposes that at these points, since the motion of electrons is not so strongly restrained as in solid solutions, the energy concentrations of the two metals are probably equal i.e. $J_A/V_A = J_B/V_B$. If n = at.-% of A and $100 - n$ = at.-% of B then $J_A/nV_A = J_B/(100 - n)V_B$ or $n = J_AV_B \times 100/J_BV_A + J_AV_B$ at.-%. The number of intermetallic compounds calculated in this way will probably be higher than those which can exist, and those compounds belonging to unstable or scarcely probable ions, and those failing to satisfy the requirements of crystal chemistry e.g. compositions in which the number of atoms of one component very greatly exceeds the number of atoms of the other, should be rejected. In the system sodium–mercury, where the ionization potentials are 10·39, 29, 65 for mercury and 5·116, 52 for sodium and the atomic values are 14·1 and 23·7 respectively; the computed compounds are as shown in Table XX.

TABLE XX. COMPUTED INTERMETALLIC COMPOUNDS OF SODIUM–MERCURY

Computed		Observed	
At.-% Hg	Formula	At.-% Hg	Formula
9	$HgNa_9$	–	–
25	$HgNa_3$	25	$HgNa_3$*
48·4	HgNa	50	HgNa
69	Hg_2Na	67·8	Hg_2Na
77·5	$Hg_{3(4)}Na$	80	Hg_4Na
96	$Hg_{24}Na$	–	–

* Actually given as $HgNa_8$

The computed values of $HgNa_9$ and $Hg_{24}Na$ are rejected.

Sodium and mercury form the following intermetallic compounds: Na_3Hg, Na_5Hg_2, Na_3Hg_2, NaHg, Na_7Hg_8, $NaHg_2$, $NaHg_4$, (see phase diagram Fig. 12).[125] A eutectic point lies at 60·5% Hg and 21·5°C., and down to this point the solubility of mercury in sodium may be represented by: $\log(1 - W/100) = 1{\cdot}5642 - 579{\cdot}85/T$ where W = wt.-% and T is expressed as °K.[1] In the liquid state there is complete miscibility.

The heats of formation of solid sodium amalgams have been determined by Biltz and Meyer,[164] Kubaschewski and Seith[165] and Kawakami.[35]

The values obtained have been critically reviewed by Kubaschewski and Catterall.[38] In view of the variety of methods used there is generally good agreement; the results of Biltz and Meyer do not deviate by more than 0·5 kg.-cal. from the selected values given in Table XXI the data in which are based on the earlier work of Berthelot[166] and Kubaschewski and Seith. At concentrations of $N_{Na} < 0{\cdot}333$, the results of Kawakami agree satisfactorily but at concentrations $>0{\cdot}4$ his results are about 1·3 kg.-cal. more negative.

The free energies of formation shown in Table XXI have been derived by Kubaschewski and Catterall from e.m.f. measurements made by Bent and Forziate.[167] Entropies of formation also given have been obtained from the above free energies and heats of formation. The negative values of ΔS refer to the formation of solid alloys from solid sodium and liquid mercury; if the entropy of fusion of mercury is introduced, the entropies of formation of $NaHg_2$ and Na_3Hg_2 are slightly negative, and those of the other compounds positive between 0·25 and 0·75.

Volume changes on alloy formation, ΔV_T, where $\Delta V = (V \text{ alloy} - \Sigma V \text{ metals})/\Sigma V$ metals at temperature T, are also given in Table XXI and these values have been taken from Vanstone[168] and Biltz.[169]

ΔS_T is expressed as g.-cal./degree/g.-atom.

The data given by Kubaschewski and Catterall[38] in Table XXII for liquid amalgams has been obtained from the following sources.

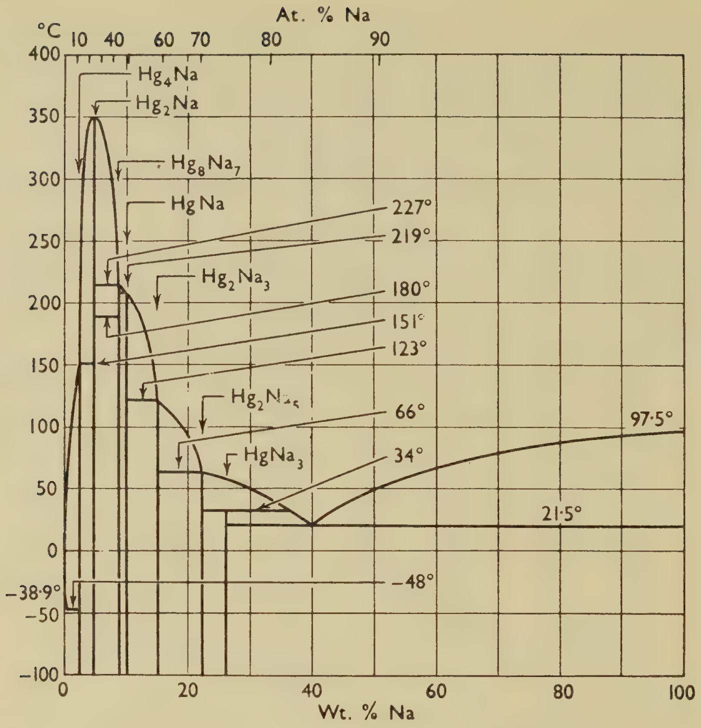

FIG. 12. EQUILIBRIUM DIAGRAM Na–Hg

TABLE XXI. HEATS OF FORMATION OF SOLID SODIUM AMALGAMS

Compound	ΔH_{298} g.-cal./g.-atom	ΔG_{298} g.-cal./g.-atom	ΔS_{298} g.-cal./deg./g.at.	ΔV_{298}
$\frac{1}{5}$ $NaHg_4$	−4000 ± 200	−3660	−1·14	−0·14
$\frac{1}{3}$ $NaHg_2$	−6000 ± 250	−5500	−1·68	−0·19
$\frac{1}{15}$ Na_7Hg_8	−5300 ± 250	−5160	−0·47	−0·21
$\frac{1}{2}$ $NaHg$	−5150 ± 250	−4940	−0·70	−0·205
$\frac{1}{5}$ Na_3Hg_2	−4600 ± 200	−4210	−1·27	−0·16
$\frac{1}{7}$ Na_5Hg_2	−3300 ± 250	—	—	—
$\frac{1}{4}$ Na_3Hg	−2900 ± 300	−2800	−0·15	−0·15

Measurements of e.m.f. have been made by Shibata and Oda[170] for amalgams containing up to 5 at.-% of sodium. The partial free energies $\Delta\bar{G}_{Na}$ (solid) (25°C.) are based on these results and a single determination by Lewis and Kraus[171] for an amalgam containing N_{Na} = 0·0175 at room temperature. The values of $\Delta\bar{G}_{Na}$ (liq.) (375°C.) have been derived from the work of Hauffe[172] who has measured the e.m.f. of sodium–sodium amalgam cells for N_{Na} = 0·45 – 0·93, with sodium-glass as electrolyte at 299°C. and 375°C. The partial free energies $\Delta\bar{G}_{Hg}$ (liq.) (335°C.) have been derived from the work of Bent and Hildebrand[173] who have measured the pressure of mercury over amalgams containing up to 48 at.-% of sodium at 335° and 375°C. Both $\Delta\bar{G}_{Na}$ and $\Delta\bar{G}_{Hg}$ are expressed in calories.

Since e.m.f. data obtained by Hauffe and Bent and Hildebrand refer to two temperatures only, the temperature coefficient and hence the partial heats of solution cannot be assumed to be accurate. In order to combine the partial heats obtained at room temperature with those obtained at higher temperatures it has been assumed that ΔC_p is zero because of lack of data to the contrary. In Table XXII $\Delta\bar{H}_{Na}$ (liq.) (g.-cal.) values for N_{Na} less than 0·06 have been derived from the results of Shibata and Oda (25°C.) and those for N_{Na} >0·4 from Hauffe (299–375°C.). Kawakami's results for the integral heats of mixing for liquid amalgams, where N_{Na} <0·14 at 110°C., have been used together with a value obtained by Roos,[174] from the heat of formation of solid $NaHg_2$ and from its heat of fusion (Lf = 2060) determined by the duration of arrest-points on cooling curves, and with the $\Delta\bar{H}_{Hg}$ values to derive $\Delta\bar{H}_{Na}$ for N_{Na} = 0·1 - 0·4. It is considered that the heat data given in Table XXII should be checked experimentally.

TABLE XXII. THERMODYNAMIC DATA FOR LIQUID Na–Hg SYSTEMS

Values in parentheses are liable to error

Volume changes on formation of liquid amalgams have been determined by Vanstone[168] and appear to be independent of temperature.

The preparation of sodium amalgams has been described by several authors. Amounts up to 15 kg. have been obtained by melting sodium under toluene in a steel vessel fitted with a loose lid carrying a thermocouple pocket, which can also be used as a stirrer, and a lead through which mercury is slowly added. During the early stages there may be bursts of flame or even slight explosions but these do not lift the lid; the latter portion of mercury may be added more rapidly. The whole apparatus must be well ventilated with a hood to carry away mercury vapour which may escape from the vessel. When the amalgam is completely melted it is stirred and poured into a round-bottomed kettle to cool.[175] A detailed study of the formation of sodium amalgam by electrolysis of sodium chloride solutions has been made by Tesh and Woodward[176] using various types of platinum electrodes. The most satisfactory results are obtained with unplatinized platinum electrodes. The effect of current density, voltage, temperature, and concentration of the electrolyte have been studied. In the formation of sodium amalgam from sodium salts by electrolysis the flat metal bottom parallel to the diaphragm and anode is inclined to the horizontal at about 1:10 and mercury flows over it. This arrangement permits the loading of the cell with a higher current density and gives the most economic yield over its whole area.[177] An apparatus for carrying out the electrolytic preparation of sodium amalgam and for its continuous reaction in a chemical process is described by de Nora.[178]

Flake sodium amalgam containing 2·75% of sodium is first obtained in the form of fine flocculi by pouring hot liquid amalgam into a jar of xylene or kerosene agitated by an electric stirrer, allowing it to settle and then drying in an air current.[179] Solidified tablets of sodium amalgam containing 23% of sodium for use as electrodes in galvanic cells are prepared and handled under oil. The hot amalgam is poured into holes in a steel plate or in an endless strip of metal and cooled in oil.[180]

An account of the electrical properties of sodium amalgams known up to 1925 is given by Schulze.[181]

Concentration changes due to the passage of an electric current through sodium amalgams have been investigated by several workers.[182-187] Electrolysis of liquid amalgams is carried out in tubes of fine bore, and composition changes along the length of the tubes determined.

For amalgams containing up to 2·1 wt.-% Na, the anode becomes enriched with sodium; for amalgams of higher sodium content, the cathode becomes enriched. Numerous tables and graphs are given.

For amalgams containing 32–35·5 wt.-% Na the electrolytic effect i.e. the difference between the percentage of sodium at the anode and cathode ends of the capillary, first increases with length of the capillary and then reaches a constant value; the effect also increases with time and then remains unaltered. The greater the content of sodium in the amalgam the greater is the electrolytic effect, and the greater the cross sectional area of the capillary the smaller the effect. The transference numbers of sodium towards the anode first increase, then decrease, pass the zero at 2·1% of sodium, then change their sign and steadily increase.[187]

Drakin[188] has stated that when an electric current is passed through a metallic phase for a short time (i.e. before the back diffusion becomes noticeable) the "transference number" $mF/It = Dc(V_1 - V_2)F_2p/RT$ where F is the faraday, m the number of g.-atoms transferred in time t by the current I; D is the diffusion coefficient, c the concentration, p the electrical resistivity and V_1, V_2 the average charges of "solvent" and "solute" ions respectively, i.e. the number of free electrons originating from a component of the alloy divided by the total number of the atoms of this component. In the system Hg–Na, $V_1 - V_2$ is 0·0286. In the steady state the concentrations at the anode, C_a, and cathode C_c should satisfy the equation $\ln(C_a/C_c) = E/T$ where E is the potential difference between the electrodes and T the absolute temperature. This equation is confirmed by the data of LeBlanc and Jäckh.[184]

When amalgams are formed by a discharge of sodium ions at a mercury cathode in a glass vessel, a wedge of electrolyte penetrates between the amalgam and the glass at a minimum potential. This is considered to be due to a very strong adsorption of discharged metal ions at the interface. The forces holding the wedge in equilibrium seem to be largely electro-osmotic.[189]

The electrical conductivities of sodium amalgams have been determined by a number of workers.[190-194] The results given in Table XXIII have been obtained at 30°C. by a potentiometric method.[193]

TABLE XXIII. ELECTRICAL CONDUCTIVITY OF SODIUM AMALGAM AT 30°C.

Wt.-% Na in Amalgam	Resistivity of Amalgam $\times 10^{-6}$	Specific Conductivity $\times 10^{4}$
0·0183	97·38	1·0269
0·0314	97·70	1·0235
0·0524	98·33	1·0176
0·0702	98·86	1·0115
0·0790	96·20	1·0395
0·1068	96·90	1·0330
0·1226	97·34	1·0273
0·1313	97·70	1·0235
0·1696	98·54	1·0148
0·1776	98·83	1·0118
0·2026	99·49	1·0051
0·2254	100·10	0·9990
0·2364	100·70	0·9930
0·2680	101·50	0·9852
0·2714	95·48	1·0473
0·2899	96·99	1·0310
0·2987	97·68	1·0237
0·3174	98·40	1·0102

Resistivity of Mercury $\times 10^{-6}$ = 96·69
Conductivity of Mercury $\times 10^{4}$ = 1·0342
